In certain tumors, particularly the sarcomas, the vessels for the most part may be mere channels in the tissue lined by a single layer of endothelial cells. The thin walled vessels are easily compressed by the growing masses of cells, and necroses and infarctions, the result of the disturbances of the circulation, are common. In many tumors hemorrhages as a result of rupture of vessels or of necrosis of their walls are seen. Necrosis also occurs as the result of imperfect nutrition, the blood supply not being able to keep pace with the rapid growth of cells. All these degenerations are found chiefly in the center of a tumor, the cells on the outside where they are closer to the blood supply are usually better preserved. In consequence of these degenerations connected with insufficient blood supply the size of a tumor may give an imperfect indication of the rapidity of growth, for the central degenerated tissue may be absorbed and replaced by cicatricial tissue which occupies but a small space. The best example of this is given in contracted scirrhus of the breast, the periphery of which may give all the characteristics of a rapidly growing tumor while the center has become converted into a mass of cicatricial tissue containing but few of the essential tumor cells.

The growth of a tumor may be rapid or slow, continuous or intermittent. A tumor may remain quiescent for months or years and suddenly take on rapid growth without any apparent cause. Rapid growth of a tumor is due to rapid cell formation, and is especially seen in those tumors in which cells and not intercellular substance form the chief constituents. Where a growing tumor comes in contact with the adjoining tissue the latter always suffers. Any tissue, be it the most resistant in the body, gives way before it. In part it may simply be compressed or pushed aside. The cells are destroyed in part by the effect of the pressure upon them, in part by the interference with their nutrition which the increased tissue pressure brings about, the compressed intercellular substance forming a capsule around the tumor, united with it by blood vessels and their accompanying connective tissue. A slowly growing tumor may produce great deformity of the surrounding tissue without destruction.

The slower the growth the greater the deformity which will be produced. Liver cells may be flattened out into long spindles around slow metastatic nodules, and I have seen the spinal cord compressed into a flat ribbon-like mass by the constant pressure exerted by a tumor of the dura. In other cases the tissue gives way without showing evidences of pressure. Cells and tissue may simply disappear when the growing tumor comes in contact with them. Occasionally the tumor cells are phagocytic, and surround and devour the tissue cells; in other cases the tissue cells seem to dissolve by contact with tumor cells. In the normal growth of bone the old bone is constantly removed by the action of large cells termed osteoclasts, which act in the same way as do the giant cells around foreign bodies. Where a rapidly growing cellular tumor comes in contact with bone this may be removed by the tumor cells acting as osteoclasts. The tumor cells are able to make stronger demands on the nutritive material which is present, and in addition their presence and contact has in some unknown way a pernicious influence on the normal tissue. The growth of the mass of a tumor is in the direction of the least resistance. In consequence of this a tumor seated near a surface of the body projects above this and is often connected with the body by a pedicle. The best examples of this are given by the tumors with expansive growth as the myomata of the uterus which may form either submucous or subserous tumors connected with the uterus by a small pedicle.

Around a tumor which grows by infiltration it is not uncommon to find smaller and larger nodules apparently not connected with the main mass. Careful examination will show in many of these cases that the separation is not complete but there is a strand of tumor tissue forming the connection. In other cases the separation is complete. These secondary masses are due to the extension of the growth along tissue spaces which offer little resistance, and when a locality favorable to greater expansion is reached a nodule is produced. Growth and tissue infiltration then proceed in the secondary nodules in the same manner as in the primary.

Under metastases we understand the secondary nodules which appear in different parts of the body and which have no connection with the main and primary tumor. These may appear in the most different organs, either singly or in hundreds or thousands, and may vary in size from a pin's head to several pounds. The metastases may be much more conspicuous and larger than the primary tumor. The metastases really represent a part of the primary tumor, and are due to cells and portions of tissue which have become separated from this and in various ways transported to different parts of the body where, being part and parcel of the primary growth, they grow with all of the characteristics of this. The conditions which they find in new regions may be so favorable that the primary nodule may be far surpassed in size. Single cells may by means of their own ameboid activity crawl along the tissue spaces and lymphatics often in a direction contrary to the course of the lymph stream and become the founders of new growths. Their progression is, however, much more frequently passive; they enter into the blood or lymph streams and they are carried in the direction of current until they reach narrow spaces, such as capillaries and lymph reticulum through which they cannot pass. The most extensive metastasis is by means of the blood vessels. The cells find their way into the blood either by growing into the vessels or from the lymph by means of the thoracic duct. Most

frequently the cells are carried into the capillaries, but larger portions, which may be separated when the primary tumor invades large vessels, not infrequently lodge as emboli in arteries of greater or less size. The metastatic growth may then be associated with the circulatory disturbance resulting from the arterial occlusion. Where the cells lodge and the metastatic nodules form depends upon a number of conditions which are only in part physical. The entry into the blood is most apt to take place in veins, and hence the most frequent metastases in blood infection is in the lungs, the cells finding here the first capillary territory. The width of the capillaries is also of influence, those of the lungs being so wide that cells of considerable size may pass through them. The blood metastases in tumors of the alimentary tract takes place from the cells being carried by the portal veins into the liver, which offers by its numerous capillaries in which the circulation is slow favorable conditions for the lodgement of foreign substances. The most abundant metastases by means of the blood are found in the sarcomas which from the close relation of the tumor tissue to the blood vessels give favorable conditions for the entry of cells into the blood. The metastases will be the more abundant the smaller the tumor cells and the greater their energy of growth. We may find cases of sarcoma in which these conditions are fulfilled in which there are countless numbers of metastases appearing in every organ of the body. In one such case at the autopsy numbers of tumor cells were found in the circulating blood. The comparative freedom of certain organs in the body from blood metastases cannot be explained solely by the varying conditions of the circulation. Metastases are comparatively rare in the ovary, the uterus, and the brain, all organs which from the large blood supply and the abundance of capillaries should be favorable for the lodgement of cells. It must be said, however, that metastases in the liver and lung are easily recognized by their variation in color and consistency, and we should not compare the frequency of metastases in the ovary and testicles with that of the entire liver or lung but with equally large areas of these organs. It must be remembered that not only must the cells effect a lodgement but they must find in the foreign situations favorable conditions for their growth.

Metastases by means of the lymphatics is, on the whole, more common than by the blood. Especially in the carcinomas the cells from the beginning are not only in close relation with the lymphatic system but actually within it. The epithelial cells of a carcinoma penetrating the connective tissue as they do must enter into the tissue spaces and by means of these into the lymph vessels. Even if we accept the prevalent view that the system of lymphatic vessels is a closed system similar to that of the blood vessels the relation of the lymph vessels to the tissue is certainly closer than is that of the blood vessels, and cells from the tissue can more easily enter into them. It is rare, for instance, that we find a carcinoma of the breast in which a careful search will not show metastasis in the axillary lymph nodes, and I have repeatedly found carcinoma cells in the lymph vessels apparently on the way to the nodes. Secondary nodules are also formed by a process termed "implantation." This takes place when the primary tumor extends to a surface and cells or portions of tumor tissue become separated and attach themselves to other parts of the surface. This is especially seen in tumors of the ovary which extend to the peritoneum. In such cases the peritoneal surface may be literally sown with small tumors which have arisen in this way. Similar implantation may take place, though more rarely, in the case of tumors growing on mucous surfaces.

The metastases give us a further example of the marvelous capacity of the tumor cell for growth. When tumor cells are carried to a different part of the body they will grow in their foreign surroundings. In this they are sharply distinguished from the other cells of the body. There have been many experiments made to imitate the metastases of tumors by transferring normal tissue to different parts of the body. Entire organs may certainly be transplanted, and if they form sufficient vascular connections they will grow and function in their new situation. Cells, however, when separated from organic connection with the organs and placed in different situations, may, for a time, show some capacity for growth, but they finally atrophy and disappear. The result is the same whether adult or fetal tissues be chosen for the experiment.

One of the unfortunate conditions met with, particularly in the malignant infiltrating tumors, is a tendency to return in the same place after operation. It is now generally believed that this return of the tumor is due to the incompleteness of removal, and as we have learned more about the mode of growth of tumors and applied that knowledge to surgical operations, return is less often seen than formerly. In an infiltrating tumor, as a carcinoma of the breast, there is no certain means of telling at the operating table how far into the surrounding tissue the tumor extends. Not only must the tumor be removed, but all the lymph vessels which may possibly contain cells of the tumor on the way to the nodes must be removed. The operator must fully appreciate the fact that the cells of the tumor represent really infectious particles, any one of which remaining in the tissue may lead to a return of the tumor. It is self-evident that at the operation the tumor must not be cut into and the cells scattered. The idea is also held that the return of the tumor is not necessarily due to presence of some of the initial tumor cells, but the tissue in which the tumor primarily arose may retain a capacity for tumor development which may lead to the formation of a tumor similar to that removed.

The division of tumors into those which are benign and those which are malignant serves a more or less useful purpose. Strictly speaking no tumor is benign. The situation of a tumor

may be the criterion of its danger to the individual. A simple fibroma, so situated that by its growth organs essential to life may be compressed and their function interfered with, may involve greater danger for the individual than would a rapidly growing carcinoma in a less important situation. The characteristics of a malignant tumor, apart from the situation, are rapidity of growth, a tendency to invade surrounding tissues, to produce metastases and to cause a condition of general malnutrition in the bearer. The benign tumors are circumscribed, their growth is slow and expansive, they can be successfully removed and do not produce metastases. The clinical importance of a tumor can usually be determined on microscopic examination. Rapidity of growth is shown by the number of nuclear figures indicative of cell division which are present. As a rule those tumors which show an excess of cells compared with the intercellular substance have more malignity but there are many exceptions. As a rule, also, the more the structure of a tumor departs from the normal structure, the more atypical it is, the greater the malignity. This is well shown in the carcinoma as compared with the adenoma. Both tumors arise from the epithelium, and this constitutes the essential element in their structure. In the carcinoma the epithelium forms solid masses and strands, the cells having no definite relation to each other and the whole structure of the tumor has no analogy with the normal epithelial structures. The cells have lost all function and even their capacity for orderly form and arrangement, retaining only the characteristic of growth. Between the masses of cells there is connective tissue which does not form an integral part of the tumor and whose chief function is to bear the blood vessels for the nutrition of the epithelial masses. Neither blood vessels nor connective tissue penetrate within the epithelial cell masses. In the adenoma the separation into epithelial cell masses and stroma is as pronounced as in the carcinoma, but the epithelial cells do not grow in an atypical disorderly manner but have the same definite relations to one another which they have in a gland. They retain to a certain degree, at least, the characteristics of their type. Owing to this typical arrangement there is less tendency for the cells to be separated from their connections and invade or be carried into the surrounding tissue. In certain situations, however, as in the alimentary canal, the adenoma may be fully as malignant a tumor as the pure carcinoma. The same departure from the normal type is seen in the sarcoma as compared with the fibroma; although arising from the same tissue as the fibroma it is atypical in being composed of cells with little or no intercellular substance. In the fibroma the cells retain their physiological property of forming intercellular substance.

That condition of general malnutrition termed "cachexia" which is so often found in the bearers of malignant tumors, cannot be explained by any single factor. It is true that the tumor cells make a stronger demand on the nutritive forces than can the normal tissues, but the withdrawal of nutrition alone cannot account for the cachexia. With the rapid cell growth of malignant tumors there is constant degeneration and absorption, and such products of degeneration have a toxic action on the body. There is also in many cases the accompaniment of intense pain due to the pressure of the growing tumor on sensory nerves, producing sleeplessness and anxiety. The greatest degree of cachexia may be observed in cases where, with these conditions, there is interference with the nutrition of the body due to the situation of the tumor, as when constriction of the alimentary canal is produced.

The study of the regeneration of tissues has shown us that like tissue comes from like. Epithelium only develops from epithelium, blood vessels only from blood vessels, etc. The formation of unlike tissue is termed metaplasia, and tissues nearly related can be formed from one another. Thus it is possible for the several simple forms of epithelium to be transformed into one another, as when the interior of the uterus becomes covered with squamous epithelium, or when islands of squamous epithelium are formed in the trachea. The various forms of connective tissue can be formed from one another. In chronic inflammatory conditions both cartilage and bone can be formed in connective tissue at a distance from normally situated cartilage and bone. Tissues wholly unlike, representing a wide differentiation, cannot pass into one another. The same holds true for the tumors. A tumor representing a definite tissue is only formed from such tissue, an epithelial tumor arises only from connective tissue. This holds good even for the differentiated epithelial structures. A tumor of the squamous epithelial type only arises from squamous epithelium, a cylindrical cell carcinoma only from a surface covered with cylindrical epithelium, a glioma only from pre-existing neuroglia. But there seem to be many exceptions to this rule. There are certain tumors which differ in all respects from the tissue from which they apparently spring. It is not uncommon to find a tumor in the kidney surrounded by kidney substance and apparently springing from this, which repeats the structure of the adrenal gland. In the same way tumors of the parotid may contain epithelium very unlike the epithelium of this gland and in addition cartilage and other structures. In tumors originating in the genital glands we may find among a variety of tissues highly differentiated epithelial structures. Then tumors are to be explained in two ways. They either develop from cells such as the germinal cells, male or female, which in themselves carry the capacity of forming the further differentiated tissue, or they develop from portions of embryonic tissue which have in the course of development become separated from their organic connections and hence do not undergo further development. These tumors of complex structure are termed "teratomas" from the analogy which they show to the malformations, or embryomas from the similarity of their tissue to that of

the embryo. As we shall see later this theory of embryonic inclusions plays an important part in the etiology of tumors.

Of the cause of tumor formation our knowledge is most deficient. The theories which have been advanced and in many cases defended with great ingenuity may be considered under three heads. First, the traumatic theory, which assumes that a tumor forms in consequence of an injury to a part. It is probable that this theory has a wider acceptance than any other. It is based largely on statistical evidence. A person presenting a tumor is asked in regard to an antecedent injury. The character of the injury and the length of time which has elapsed between its receipt and the appearance of the tumor is little considered. There is a tendency always to connect a present with some antecedent event, and careful inquiry can usually elicit a history of injury which would have been otherwise forgotten. The tendency to refer a tumor to an injury seems to me very much like the widespread belief of the laity that a malformation may be due to some event which has produced a mental impression on the mother. The examples most usually cited as evidence of the relation between tumor and trauma are the carcinoma of the lower lip in man, supposed from the habit of smoking, and carcinoma of the scrotum which develops in chimney sweepers as a result of the constant irritation produced by the soot. It is perfectly true that the carcinoma of the lower lip is much more common in men than in women and that the habit of smoking is more prevalent in men. But the traumatic theory does not explain why the tumor develops chiefly on the lower lip. Carcinoma of the cheek is, if anything, more common in women than in men, notwithstanding the more frequent injuries produced by the shaving habit. Epithelial tumors do not appear on those portions of the surface of the body which are most subject to injury. The epithelial carcinoma is comparatively rare on the hands, and almost unknown on the feet. Carcinoma of the rectum does not appear as a rule immediately at the anus, where we might suppose that injury and irritation would be greatest, but higher up in the gut and at the point where the squamous epithelium of the skin joins the cylindrical epithelium of the alimentary canal. It has been held that a trauma may act in two ways in producing a tumor. In one theory the cells may be excited to proliferation and this may continue, finally leading to the production of a tumor. The matter of cell proliferation is not as simple as it appears on first sight to be and is only one of the phenomena which the tumor presents. The surest way to produce a proliferation of cells is by an injury. Depending upon the character of the injury there may be a great difference in the degree and the character of the proliferation. The action of certain bacteria is characterized by the formation of new cells in their vicinity, and the new tissue produced may be so characteristic that we can determine from it the causative agent, as in the case of tubercle and leprosy bacilli. In other cases around a simple injury a tissue is produced which differs from the normal tissue of the part in the abundance and character of the cells, which extends considerably beyond the territory immediately injured and which has a certain similarity to the tissue of certain tumors. Certain toxic substances, particularly bacterial products, excite proliferation in tissues apparently not affected by the direct injurious action of the agent. One of the most striking examples of proliferation is seen in the lymph nodes in the vicinity of the vaccination area in vaccinia. The typhoid toxin has a remarkable influence in producing proliferation of the endothelial cells, particularly in the lymph nodes and spleen. Other agents may excite to proliferation the peritoneal epithelium or the cells lining the capillaries of the glomeruli of the kidneys. All of these examples, however, whether acting locally to the injury or at a distance, can only be regarded as in the category of regeneration. The injurious substance, whatever its nature, affects the interrelation of cells or systems of cells with each other and with the organism as a whole and proliferation takes place until the normal balance is restored. In certain cases, as between the epithelium and the connective tissue, one tissue seems to hold the other in check. In case of continued impairment of the connective tissue, the epithelium, where it comes in contact with such tissue, has the power of invading it and growing as in an epidermoid carcinoma. As soon as the limit of the injured tissue is reached the epithelial growth ceases. All of these examples are far removed from analogy with tumors. The new tissue does not continue to grow as a parasite and independently; it ceases when the integrity of the organism is restored and when the action of the agent producing the injury is removed.

In the second place it is held that the injury may lead to tumor formation, in that by means of it cells are separated from their organic connection with the tissue to which they belong and that such separated cells may assume independent characters and become the origin of tumors. Ribbert was formerly inclined to assign to such separation and displacement of tissue an important rôle in the production of tumors. There is no experimental evidence for such view. Tissues so displaced either after remaining a time are absorbed and disappear or they become permanent and grow as in their old situation. There have been a great number of such experiments in which both adult and fetal tissues have been separated from their normal connections and implanted in other parts. Embryonic and fetal tissues so displaced show a greater activity of growth than adult tissue, but finally are, like these, absorbed and disappear. In considering the effect of trauma in the production of tumors the very numerous experiments which have been made on man are usually left out of consideration. I allude to effects of surgical operations. In these the most varied injuries are produced. In most cases in addition to the acute injury involved in the incisions there is combined the chronic injury

and irritation of the sutures. Moreover, the most ideal displacements of tissue are produced. Cells and tissues in greater or smaller masses are separated and included in foreign tissue. It is probable that in every suture placed in the skin epithelial cells are dragged into the subcutaneous tissue, and this is more particularly the case in intestinal surgery. Yet I have never heard of an instance in which a tumor, with the possible exception of a keloid, appeared in the site of a suture after a surgical operation. Most surgeons, I think, hold with greater or less tenacity to the traumatic theory of tumor formation, and yet the thought of the possibility of a tumor following their traumas does not enter into their calculation. In any consideration of the traumatic theory it must be remembered that tumors of various sorts are quite common pathological conditions, that traumas are also common and that combinations of the two incidents might be frequent and striking. The theory lacks all experimental confirmation and, as it stands at present, it has much the same footing as does the theory of maternal impressions as a cause of malformation. In both there are many striking coincidences.

Another theory which has had many defenders in the past two decades, though less now than formerly, is that of living parasites being the cause of tumors. In the first place an analogy was sought between certain of the infectious diseases, especially tuberculosis, and the malignant tumors. At first sight the analogy seems striking. In both there is a characteristic tissue produced, and a primary focus from which the disease extends, the extension taking place by means of the blood and lymphatics. There is, however, this striking difference: In the case of the tubercle there is an agent, the tubercle bacillus, which is carried to various places and excites proliferation in the various tissues leading to the formation of the tubercle. In the malignant tumor it is the tumor cell which is carried from place to place and this does not excite proliferation but itself proliferates. The cancer cell has its analogy not with the tissue which is produced by the bacillus but with the bacillus. The part which the tissue plays is to act as a host, in greater or less degree hospitable to the invader. The tissue reaction which is often seen around a tumor metastasis is the analogue with the tubercle. That it is the tumor cell to which the metastasis is due is an easily observed fact. In favorable cases it is possible to follow the formation of a metastatic nodule from a single cell, and isolated cells are often found in the lymphatics and blood vessels on their way to lodgement and metastasis production.

Support was found for the bacterial theory in the fact that cultures made from tumors often showed the presence of bacteria. It was soon found, however, that these bacteria were not specific, that they were found chiefly in tumors to which bacteria had access by ulceration and that they represented nothing more than common, invading wound bacteria. As we have become better acquainted with the different classes of infectious agents each class in turn has undergone the odium of accusation as the etiological agent of tumors.

Following the bacteria the blastomycetes had their turn. They were not only found in tumors as were the bacteria but tumors were said to be produced by the injection of pure cultures into animals. Certain of these organisms are infectious for animals; they find in their tissues conditions favorable to their growth and produce circumscribed nodules varying in size which to the naked eye greatly resemble tumor metastases. As in the tubercle, histological examination shows that the nodule is composed of actively multiplying organisms and cells coming from the tissue.

The protozoa seemed to offer a still more favorable field for etiological quest. Many of these are intracellular parasites, and in the course of their cyclic development they assume a variety of forms within the cell. No infectious agent produces a lesion which seems to have such an analogy with the tumor as in the coccidial disease in the rabbit's liver. The organism here enters the epithelial cells of the bile ducts. These cells proliferate with great rapidity, papillary ingrowths into the ducts are formed and circumscribed nodules are produced which have, both to the eye and microscopically, a striking similarity to papillary and intracanalicular papillomata. But the cells of the nodule are not infectious; they are produced by the action of the coccidium, and apart from this organism they have no independence. The striking morphological changes which are produced in the development cycle of the coccidia also led to the belief that certain small bodies, often found included in tumor cells, chiefly in carcinomas, were forms in the developmental cycle of some protozoan. As knowledge of the protozoa increased and better technical methods for their study were developed this has appeared always more improbable. There are undoubtedly certain microscopic things often found included within tumor cells the nature of which we do not know. Their character probably varies; some of them show similarity in form and size and seem of the same character, but others vary in all respects. Nothing approaching a protozoal cycle has been made out, and the inclusions are best explained as products of cell and nuclear degeneration, or products resulting from inclusion of other cells, or products of cell secretion.

And finally the spirocheta have had their turn. They have been described in the transferable tumors of mice and in turn shown to be a common reinfecting organism in the mouse, and their occasional presence in tumors to be explained as is the occasional presence of bacteria. Further support of the infectious theory was given by the discovery that the tumors of certain animals are inoculable. Carcinomata of mice are inoculable and a few other tumors, both carcinomas and sarcomas, have been found in rats which were capable of transmission. In the ordinary inoculation procedure small pieces of tumor are rubbed up into an emulsion which is injected beneath the skin, or a small piece of tumor tissue is placed in an incision beneath the skin. But this has been shown to be very different from the transmission of an infec-

tious disease. The infectious disease is transmitted by transferring to the inoculated animal the cause, and this growing in the tissue produces the lesions by its reactions on the tissue. In the transference of the tumor the tumor cells grow in the inoculated animal just as they would grow in a metastasis. It is here again the tumor cell which has the capacity of a parasite, and not an inoculation of an infectious agent, which causes the tumor cell to form. The only parasite it would be possible to conceive of would be one living within the cell and transferred with the cell. The defenders of the parasitic theory seem to have had in mind only tumors of the carcinoma type.

But all tumors have so much in common that any cause must be equally applicable. Moreover; there must be a different cause for every tumor, certainly our knowledge of infectious diseases forbids us to believe that the same parasite can in one instance produce a carcinoma, in another a fibroma, and in another a teratoma. The parasitic theory could give us no explanation whatever of the congenital tumors. Take the example of a congenital tumor of the kidney, in which the tissue more closely resembles the Wolffian body than it does any adult tissue, or the congenital tumors of the retina in which there are embryonic neural structures, or the glioma of the coccyx in which neuroglia is found far removed from its normal situation, and it is impossible to think of an infectious agent producing such formations.

Some analogy has even been sought in the comparison of the infectious nodular growths in plants with true tumors. These, however, are not tumors except in the sense that the coccidial nodule in a rabbit's liver is a tumor. Again, tumors seem to be more common in those organs of the body which are most secure from their structure and situation from ordinary infections. Apart from the accidents which may happen in pregnancy and lactation there are few infections which have their seat either in the uterus or in the mamma. It would be useless to go on enumerating the arguments against infection by living organisms being considered a cause of tumors. Every theoretical consideration is against the theory and not one proven fact has been shown as a substantiation of the theory. It is, however, interesting to see how stimulating to knowledge an hypothesis even with so little in its favor may be. It was brought forward at a time when the limits of pure anatomical research on the subject by the methods then in use seemed to be exhausted. It served to stimulate the imagination and to again turn the attention of able investigators to renewed research, and the most important of the knowledge we have on tumors may be traced to the influence of the hypothesis. The literature on the subject, both pro and con, has reached an extent that it is almost impossible for one to control it. It would be absurd to say that the hypothesis cannot be true, but if an infectious living organism be found, which will produce a growth having all the characteristics of a true tumor it must be an organism of a different class, and act in a way at variance with all we know of the action of infectious organisms.

The third theory of tumor formation is that known as the embryonic or germinal theory. This theory has so far held its ground much better than either the traumatic or the infectious theory. Although not original with Cohnheim it was advanced and defended by him with so much vigor as to have become known as the Cohnheim theory. Briefly stated, this theory assumes that in the course of embryonic development, certain of the tissues do not undergo perfect development but remain in an imperfectly developed or embryonic condition and are included within the developed tissues. It is assumed, further, that in the course of embryonic development in the opposing intergrowth of tissues, and in the complexities of tissue formation which then take place, such separation of embryonic tissue easily takes place. Such separated tissues will then be abnormally situated or included in other parts, and may go on to complete anatomical or functional development as is seen in the accessory spleen, adrenal gland, and pancreas, or they may remain undeveloped or imperfectly developed. Such embryonic or imperfectly developed portions of tissue withdrawn from the influences of the interrelations of parts would be capable of life as independent of the organism as a whole as a parasite would be. The cells would retain the embryonic capacity of growth and be free from the restrictions of growth which are imposed upon tissues by their relations with each other and with the body as a whole. This theory brings the subject of tumors in close accord with the malformations, in thus referring them to an embryonic origin. This theory accords best with what we know of tumors, and so far as I know there is nothing incompatible with it. It is perfectly certain that in embryonic development such separations of tissue not infrequently take place, and also certain that tumors do develop from such separated parts. Thus we may find portions of fully developed adrenal tissue included either in the capsule or in the cortex of the kidney, and we also not uncommonly find tumors in this situation which have the characteristics not of the kidney but of the adrenal gland. Even tumors which are seemingly of glandular origin often do not arise in the substance of glands but in tissue adjacent to but not connected with the gland. A great many examples might be cited as evidence that tumors frequently originate in such misplaced tissues, but the theory does not give a complete explanation. It does not explain the growth; it does not show why these misplaced tissues develop into tumors; why the development is associated with certain periods of life; why it is not possible to produce tumors by the artificial inclusion of embryonic tissue; why the inoculation of tumors succeeds only in certain animals. To this hypothesis as to the origin of tumors which seems to have so much in its favor there must be added another as to cause. We must assume that at a certain period these germinal remains gain a power which enables unrestricted growth to take place, or what amounts to the same thing, the other tissues lose their power of restraining and

regulating growth. It would be impossible in the limits of this paper to enter into a consideration of this part of the subject.

Nor will it be possible for me to take up the subject of the experimental study of tumors which is being actively prosecuted in a number of laboratories and by men well qualified for research. It is from such experimental study in which all of the conditions can be controlled that we have most to hope. The subject of tumors is, further, one of general biological interest and should be attacked by the embryologists and zoölogists who bring to the investigation both new methods and new points of view.

STENOSIS OF THE PYLORUS IN INFANCY.*

BY CHARLES L. SCUDDER, M.D.,
Surgeon to the Massachusetts General Hospital: Lecturer on Surgery, Harvard Medical School.

We all are more or less familiar with stenosis of the pylorus in adult life, whether it be caused by a benign or a malignant lesion. Stenosis of the pylorus occurs also in young babies. It presents a unique pathology — benign in its anatomical characters but most malignant in its fatality. It occurs with greater frequency than is generally supposed. It is too often overlooked. The diagnosis is sometimes confusing. One type of the disease is almost invariably followed by death if treated unintelligently.

It is for these reasons that I propose to present for your consideration the salient facts concerning stenosis of the pylorus in infancy and its surgical treatment. These are subjects of the very greatest practical importance to the general practitioner of medicine, the pediatrist and the surgeon.

FREQUENCY.

Scudder and Quinby, in May, 1905,[1] two years ago, analyzed all cases of this disease. During seventeen years' literature, since 1888, 115 cases were recorded, 55 autopsies and 60 operations. Since this time, during the past two years, from May, 1905, to May, 1907, about 40 cases have been reported. Papers upon this subject have contained the records of isolated cases treated medically and surgically. No very important addition to our knowledge of the subject has been made during this time.

The pathologist at autopsy and the surgeon at operations upon the living baby have together convinced all hitherto doubting pediatrists and internists that this disease exists as a distinct entity and that it demands active consideration in the differential diagnosis of the acute abdominal diseases of early life. In those communities in which there exists an accurate knowledge of this disease cases are being repeatedly discovered. Stenosis of the infantile pylorus is not uncommon.

* Read at the Annual Meeting of The Massachusetts Medical Society, June 11, 1907, Section in Surgery, and at the Annual Meeting of the Dubuque (Iowa) County Medical Society, June 18, 1907.

[1] The Jour. of the Amer. Med. Asso., May, 1905.

PATHOLOGY.

The findings are constant and uniform. Occupying the position of the normal pylorus is a tumor, small, smooth, oval, hard, movable and without adhesions. The tumor varies in size, averaging that of a hickory nut. This tumor has a constant structure — a hyperplasia of the circular muscular fibers of the pyloric segment. There is also either an hypertrophied or a thinned stomach wall, occasionally a dilated esophagus, a narrowing of the pyloric lumen, an hypertrophy of the mucous membrane and a collapsed empty intestine.

ETIOLOGY.

The cause of the hyperplasia of the circular muscular fibers is unknown. There are three hypotheses suggested to explain the conditions:

1. That of Pfoundler — a spasmodic contraction due to post-natal gastric irritation.
2. That of Nicoll — a simple overgrowth of the sphincter muscle of the pylorus.
3. That of Thompson — an inco-ordinated action of the stomach muscles dependent on functional disorders of the gastric nervous system, resulting in gastric spasm.

A discussion of the etiology is fascinating but unprofitable.

CLINICAL PICTURE.

An apparently healthy breast-fed child is born. Upon the third or fourth day he vomits whatever he may have taken from the breast. The vomiting continues at irregular intervals, and is evidently independent of the quality of the food. The child loses weight. All kinds of artificial foods and modifications (home and laboratory) of cow's milk are used without permanent success. He wastes away, weakens and dies.

The cause of death affixed to the certificate is one of the following: "Infantile atrophy," "Gastric irritation," "Sub-acute gastritis," "Inanition," "Chronic gastritis," "Gastro-intestinal catarrh."

If in cases of this kind observations were made with accuracy the following significant facts would often be found: the baby's tongue is perfectly clean; the breath is sweet and natural; the appetite is a little less ravenous than usual; though hungry he doesn't feed greedily, he is soon satisfied.

After feeding, the baby shows signs of abdominal discomfort, his face is covered with grimaces, he wriggles about uneasily, he even cries wth evident pain, he then vomits. The vomiting is very forcible, through the nose as well as mouth; is often mistaken for a simple regurgitation from a full stomach. The hypertrophied stomach wall contracting violently against the obstruction at the pylorus causes the gastric contents to be expelled forcibly through the relaxed cardiac orifice.

The frequency of the vomiting is dependent upon the number of feedings and upon the amount taken at a feeding. The quantity vomited varies

with that received into the stomach. The material ejected is the milk and food taken. There is usually no bile, no mucus and no blood in the vomited material. There is almost never hyperacidity of the stomach contents. After the vomiting the baby is quiet and sleeps until he next feels hungry.

If the abdomen is carefully palpated a distinct tumor may be felt above and to the right of the umbilicus. This tumor being small and partly covered by the liver is not always readily felt. An enlarged mesenteric gland has been mistaken for a pyloric tumor. If the abdomen is inspected in a good light immediately after a feeding, a strong gastric peristalsis will be noticed. This was very evident in two of the cases I have to record.

The dejections are somewhat variable in character, but because of the slight amount passing through the pylorus they are small and meconium-like, occasionally fecal in character, at times watery.

The stomach will be found dilated in proportion to the duration and degree of the obstruction. Epigastric fullness and a sunken lower abdomen are suggestive.

The child loses in weight despite treatment, because of starvation.

DIAGNOSIS.

Characteristic vomiting; a pyloric tumor; visible gastric peristalsis; gradual and progressive loss in weight despite skilled feeding; this sequence of these signs is significant. An absence of a *seemingly important* sign is of comparatively little consequence. The total picture is most suggestive.

The obstruction to the pyloric lumen caused by the tumor is variable. Difficulty in diagnosis is measured by the degree of obstruction. There is little doubt about the diagnosis if the obstruction becomes complete. If on the other hand the obstruction is incomplete or partial, there will be doubt.

An obstruction may result from a tumor at the pylorus, also from a spasm of the pyloric muscle independently of tumor formation. The symptoms may simulate a chronic gastric indigestion. Each of the signs found in cases of pyloric stenosis may be present in cases of infantile indigestion, but the particular quality and sequence of symptoms characteristic of pyloric stenosis are absent. The completed picture is wanting. Vomiting is not always symptomatic of obstruction in young babies, cerebral disease may be imminent. There is little danger of confusing an intestinal indigestion with pyloric stenosis.

Pyloric stenosis in infants if untreated is usually fatal. A few cases are reported in which medical treatment is said to have effected a cure. Unfortunately no medically treated case has been demonstrated to have had the disease. Surgical treatment has cured more than half of these desperate cases.

OPERATIVE TREATMENT.

The degree of the obstruction and the general condition of the child should be the basis for treatment. The cases arrange themselves into three groups:

1. The obstruction is evidently complete or almost complete — operation is demanded at once.

2. The obstruction is partial and the child is not doing well and is losing weight — operation is likewise indicated.

3. The obstruction is partial and the child is doing fairly well, and is not rapidly losing weight. With this third group one may be justified in experimenting with medical treatment, but only for a short time. It must always be remembered that remissions of symptoms occur. Improvement may be but temporary; the strength of the child must not be allowed to greatly diminish before operation is done. In this third group (in which obstruction is partial, and the child is doing pretty well under medical treatment) are found the so-called cases of "pyloric spasm" which are supposed to yield to medical coaxing. Such is the case reported by J. L. Morse, in September, 1906.[2]

It is more and more evident that prolonged medical treatment of certain of these cases is irrational. The risk and danger to the child's life is often greater than if operative treatment were instituted early. Heubner of Berlin presented a series of cases all treated medically without operation. His mortality rate is low. I believe, from a careful analysis of his cases, that deductions cannot be drawn from his 21 cases till they are followed a longer time. It is questionable if he had to do with true pyloric stenosis.

There are very real dangers attending the treatment of this disease. The immediate danger is apparent, viz., the letting slip the opportune time for operation, misjudging the condition of the child. The later danger is that there may occur in youth and in adult life gastric difficulties dependent upon the persistence of infantile conditions. Instances are recorded by Beardsley, Sonnenberg, Hansy and Shaw which make this latter possibility very real. Both of these dangers are probably eliminated by operation.

The mortality following operation still remains high — but the mortality of operation upon weak and wasted infants will always be large. Many different operators with varied technique and the consequent absence of exactness will always record a high mortality in these desperate cases. An exploratory laparotomy upon a young infant in which the diagnosis is in doubt, and in which improvement has ceased, is certainly wise. I have to record one such exploration. The operation of choice in cases of pyloric stenosis is a posterior gastro-enterostomy, done with clamp and suture. The Loreta operation of divulsion and pyloroplasty are two other procedures thought well of by some.

There is little doubt of the existence of cases

[2] BOST. MED. AND SURG. JOUR., Sept. 27, 1906.

which simulate pyloric stenosis with tumor, and which improve and apparently recover under some one or more of the following procedures: resting the stomach; lavage of the stomach with weak alkalis; warm abdominal poultices; nasal tube feeding; the administration of opium and atropine; the giving of opium before feeding (one eightieth of a grain); the use of alkalis; experimentation with food by changes, both in quality and quantity; rectal feeding.

That there actually are cases[3] of pyloric stenosis with tumor, which have recovered completely under medical treatment has not yet been demonstrated. Until this demonstration is made, I prefer the certainty of surgical treatment to the uncertainty and very high mortality of medical experimentation. Seefish in 1904 mentioned three cases which "recovered" under medical treatment, and were all operated upon before twelve years of age. Surgical supervision of medically treated cases will help to diminish the large mortality of cases treated medically.

From my own limited experience of the past two years, I have to report 5 cases. I will not at this time relate these cases in detail (two have been previously recorded), but will mention briefly certain facts of interest concerning each.

In the first case operative treatment was withheld because the child was moribund. The stomach of this child exhibited at autopsy a typical pyloric tumor and an hypertrophied stomach wall.

In the second case an exploratory operation was done upon a very sick child, and the tumor was not present. The child has since recovered, and is, after a stormy experience with various foods, increasing in weight.

Of the 3 remaining cases, in each of which a posterior gastro-enterostomy was done:

Case III[4] has the distinction of being the youngest case yet operated upon; he was fourteen days old. He had been artificially fed. The stomach was not very large.

Case IV[5] was twenty-four days old. He had vomited from the third day after birth. The stomach wall was thickened. He had been breast fed.

Case V [recorded here for the first time; to be reported in full elsewhere] had likewise been breast-fed. He was twenty-two days old. The stomach wall was edematous, and markedly thickened in the pyloric part.

In the last 3 cases the signs of the disease were typical. The tumor was characteristic. All 3 cases recovered from the operation. All have been followed, and each child is now robust and well, two years, one year and ten months, and seven months, respectively, since the operation.

Sufficient time has now elapsed to make it possible to know the real results of a gastro-enterostomy in these cases. I have succeeded in determining the condition of certain cases of other observers several years after operation. The cases of Abel, Löbker, Fritzsche, Kehr, Schotten, Giles, and Stiles, quoted in the original paper,[6] are alive and well; four of them six years, one four years, one three years, and one two years following operation. These results are significant. They demonstrate: 1, that these presumably otherwise normal children have escaped the difficulties of obstruction; 2, that nutrition does not suffer following gastro-enterostomy in cases of infantile pyloric stenosis. Posterior-gastro-enterostomy is an effective measure under these conditions.

These cases of gastro-enterostomy following pyloric stenosis in early life form a series of great experimental value. The operation is done under almost normal physiological conditions, excepting for the mechanical obstruction. Presumably no other disease exists in these tiny new-born individuals. There is very little disturbance of digestion. The results are absolute. The effects produced by the operation are uninfluenced by disorders of digestion and other diseased states so commonly found in adults. These results, therefore, go far to confirm and substantiate the evidence accumulating from adult cases that posterio-gastro-enterostomy properly performed is physiologically harmless. Pyloroplasty and gastroduodenostomy, whether of the Kocher or Finney type, are theoretically and physiologically ideal procedures. Posterio-gastro-enterostomy is proved to be physiologically satisfactory, and in these cases of infantile stenosis is certainly anatomically the choice of all procedures. Whether the obstructed pylorus recovers itself after the gastro-enterostomy and functionates naturally after a time is as yet undetermined, because there are no records of autopsy findings long after operation. Katzenstein by his study of alterations of stomach digestion following gastro-enterostomy and Joslin's studies in metabolism of fats lead one to view with interest these cases of gastro-enterostomy in infants, particularly with reference to the subsequent nutrition of the individual. No instance of peptic jejunal ulcer is recorded following a posterior gastro-enterostomy for pyloric stenosis in infancy.

I may be pardoned if I mention here some of the practical matters which one treating these cases surgically will find helpful.

Preparation of the baby for operation. — The baby is weak. A nutrient and stimulating enema containing salt solution and whiskey, to make ℥ij, given very slowly through a soft rubber catheter, will help the child remarkably, especially if there is time to repeat it before operation. The stomach need not be washed out, for the vomiting which has persisted has usually left the stomach empty. The skin of the abdomen is very sensitive. Local preparation should be restricted to bathing the abdomen after etherization, first with castile soap and water applied

[3] Such are supposed to be the cases recorded recently by Reinach, Marx, Murdock, Morse, Harper, Griffith, Sutherland, Hutchinson, Neild, Rob, Crahim, and Heubner, all carefully observed and each treated by medical means. The cases have been followed and are known to be free from all signs and symptoms of gastric disturbance from several months to two and one-half years after treatment ceased.

[5] *Ibid.*, Feb. 22, 1896.

[6] Jour. of the Amer. Med. Asso., May, 1905.

with a gauze sponge (green soap is to be avoided) and then with warm 70% alcohol. The arms and legs are to be covered with sheet wadding or an equivalent, secured best by a little bandaging. The baby may lie upon a blanket, underneath which are two or three warm water bottles, the water not being warmer than 100° F.

The *anesthetic* is preferably ether only. This should be administered by a most skilled anesthetist. Little ether is needed after the abdomen is opened. It is essential that the anesthetic be continued sufficiently to preclude the likelihood of a prolapse of gut from the wound. There is very great shock to a little baby from over etherization.

The *instruments* should be adapted in size to the very small parts to be manipulated. Small short-toothed forceps and small scissors should be used for work upon the gut. Retractors are not needed and their use should be avoided. Retractors may increase shock, traumatize the wound and stimulate post-operative adhesions. I believe that a small clamp is efficient in preventing hemorrhage from the bowel wall, in diminishing soiling of the peritoneum by intestinal contents, and that it facilitates the suture. A needle holder is unessential — it's a time consumer — the fingers make the best needle holder in the operation of gastro-enterostomy. A zero or double zero chromic catgut is satisfactory for the inside intestinal suture, while a fine Pagenstecker linen thread is secure for the inside suture in the gastro-enterostomy.

THE OPERATION PER SE.

The *abdominal wall* is extremely thin. The abdomen may be opened unexpectedly. The *liver is large*. The median incision will be best made both above and below and to the left of the umbilicus. The incision should be large rather than small, perhaps three inches long. The small opening necessitates greater handling of the abdominal contents. The little larger opening enables the operator to secure the jejunum very readily without the trauma of much handling. Nothing should be removed outside the abdomen excepting the parts to be operated on, the stomach's posterior wall and the jejunum. The great omentum, containing little or no fat tissue, is drawn upward as a thin film from over the intestines. Care should be exercised lest the very transparent and veil-like thin gastro-colic omentum be incised too vigorously and the stomach wall itself suffer by being nicked by the knife. The *mesentery of the jejunum* is short in proportion to the width of the gut as compared with the adult mesentery, consequently it is with difficulty at times that the intestine can be brought forward to the anterior stomach wall for an anterior gastro-enterostomy without constricting the transverse colon unduly. In my cases I have made no loops, and have placed the stoma near the origin of the jejunum. The *stoma* in the infant's intestine should be from three-fourths to one inch long when sutured. If a very large stoma is made, obstructive difficulties may be caused by the wall of the gut opposite the stoma blocking its lumen, as suggested first by Cannon. This I have had happen following gastro-enterostomy upon cats. After suture, the parts are returned to their natural places so far as possible, the jejunum to the left of the spine.

In *closing the abdominal wound* no attempt should be made to close by layers. Through and through sutures of silkworm gut are satisfactory. These sutures should not be drawn too tight, for the suture cuts its way through the young skin readily. Some one has suggested that these sutures be tied over bits of tiny rubber tubing to prevent them cutting the skin.

In placing the *sutures* the needle should avoid wounding the large vessels of the suspensory ligament of the liver which may lie very close to the right edge of the wound. The sutured wound is covered with a gauze sponge, and the abdomen is supported by two or three narrow straps of zinc oxide adhesive plaster. Traction on the sutures is reduced thus to a minimum. The position of these plasters may be changed to avoid their chafing the skin. An ordinary binder helps to support the abdomen.

AFTER OPERATION.

Feeding the baby. — The importance of the proper feeding of these tiny little babies after operation for pyloric stenosis cannot be overstated. If the intestinal suture is well placed, the stoma is strong and is in less danger of leaking at first than after some ten days. It is common experience with suture of the intestine in the adult that the second week is the time of death from leakage. The feeding should, if practicable be in the hands of a skilled feeder of babies. Breast milk is the ideal food. Difficulties arise rapidly if an artificial food is needed. The amount to be allowed at each feed must be tentatively determined; fairly large amounts are usually well borne immediately after the operation. The baby is in great need of water, and it is a mistake to keep the total quantity low, especially if the food used agrees.

If breast feeding is possible the baby is allowed to nurse for two minutes at first. The time is gradually lengthened. If breast feeding is impossible it is best to begin with a whey, half ounce every two hours. Two days later may be used a weak modified milk, 2% fat, 5% sugar, 5% proteid, 5% lime water, and equal parts water. Gradually one may increase the richness of this mixture. Post-operative rectal feeding may be needed for a few days. Salt solution enemata are helpful.

The *temperature* is often high, even though there is no evident sepsis. In two of my cases the temperature immediately after operation was 104° F. and 105° F. It represented a normal reaction to this operation. This temperature gradually dropped during six days and then remained normal.

Even though the operation is done upon a weak baby it is not productive of great *shock*. The

baby behaves very much in this particular as the adult after a stomach operation.

Vomiting does not cease with the operation. Vomiting persists for several days and ceases gradually. There was no vomiting in my first case (No. 3) after seven days; in my second case (No. 4) after six days; in my third case (No. 5) after about six days. This post-operative vomiting is less forcible than the vomiting previous to operation, and of course contains a little bile, and may contain a little old blood the first twenty-four hours. The post-operative vomiting may cause a breaking open of the wound, unless it is carefully sutured, with resulting prolapse of the intestine. This has happened in a few reported cases. In one case with which I am familiar replacement of the gut under ether was followed by a perfect recovery.

From the anterior abdominal wound may start an oozing of *blood* the second or third day. This occurred in one of my cases (No. 5). It was difficult to control this oozing until a suture was taken through the whole abdominal wall. The amount of blood lost was not great, but was sufficient to make an appreciable difference in the facies of the child. Little babies bear a hemorrhage poorly.

There may be considerable *abdominal distention* following operation. This is relieved by small suds and glycerine enemata. In one case (No. 2) of exploratory laparotomy, six days after birth, there was considerable difficulty in keeping the sloughing *umbilical cord* from infecting the abdominal wound at the time of operation. Immediately after operation the cord was kept dry with boracic acid powder and neither a primary nor a secondary infection occurred. A few cases are recorded in which convulsions followed operation. These convulsive movements may be allied to the cases of gastric tetany occurring in adults. One case with which I am familiar recovered after these convulsive attacks.

Hernia, or a bulging of the abdominal wall at and in the region of the cicatrix, has occurred in two of my cases. This bulging has not proved sufficiently great to demand operation. A snug abdominal binder should be worn for one year after operation. The suture had best be removed on about the seventh day, or before much cutting of the skin is present, and the abdominal wall supported by zinc oxide adhesive plaster strips. In no group of cases with which I am familiar is the elimination of all the causative factors of shock so rapidly effective in establishing convalescence as in these cases of infantile pyloric stenosis.

Speed, implying familiarity with one's technique; absolute asepsis; hemostasis; a minimum amount of handling of the gut; an absence of trauma to the abdominal wound; conserving the body heat — these are the requisites of success in operations upon these tiny individuals.

THE Pasteur Institute of Minnesota at Minneapolis is fully equipped and ready to receive patients.—*Journal American Medical Association.*

LEAD POISONING IN A RURAL COMMUNITY.*

BY WILLIAM N. COWLES, M.D., AYER, MASS.

THE purpose of this paper is to give an account of my experience with lead poisoning among the people of several country towns in my vicinity, viz.: Harvard, Shirley, Littleton, Acton and Ashby, Mass.

The persons affected have been chiefly residents of farm houses, using water drawn from wells or springs through lead pipe. I have observed the cases during the last ten years, at first rarely, but later with increasing frequency, as my interest in the subject and ability to recognize the condition in its various forms have increased.

No attempt will be made to treat of lead poisoning in general. The cases will be related as briefly and with as little detail as possible, consistent with establishing the nature of the affection, and the extent and variety of the damage due to this intoxication.

Mrs. W., sixty-six years of age, consulted me in June, 1899, on account of what she called rheumatism; she was well and active until her present illness. The trouble began eight months before, in the hands, soon spreading to the shoulders, neck, feet, and knee and hip joints, becoming all the time steadily worse.

The finger and wrist joints were swollen and stiff; there were pain and tenderness in the course of several large nerve trunks, both brachial regions being affected.

The pain was much worse at night; she walked with difficulty on the level and could not ascend steps without help; she could not dress her hair, and fed herself with difficulty. There was no apparent paralysis. Lead poisoning was suspected, but inquiry showed that the water supply at her house was drawn from a well by means of a well-sweep and wooden bucket.

No source of lead could be discovered after persistent inquiry, until the patient recalled that about two years before an old lead clock-weight had been accidentally dropped into the well. The well was pumped free of water, and the clock-weight found and removed. In two weeks Mrs. W. noticed an improvement in her lameness, and in four months she was entirely well. She lives at the same place and uses water from the same well, but has had no return of the lameness.

This piece of lead has about 32 square inches of surface. The smaller sizes of lead pipe have more surface than this for each foot of length.

Lead pipe in a well usually goes several feet under water, giving many times the surface of this weight for solution of lead from the *outside* of the pipe.

G. H. C., forty-six years of age, lived with his family on a farm in New Hampshire, for twelve years, from 1891 to 1903, using spring water carried by lead pipe. In April, 1903, he moved to a farm in Littleton, Mass., where he also used spring water running through lead.

In the fall of 1904, a year and a half after moving to Littleton, C. began to be troubled with shortness of breath on exertion. His heart was enlarged, and his radial and temporal arteries tortuous and thickened. A year later lead poisoning was suspected; lead was found in the water used by the family, and iron pipe was put down in place of the lead. Seven months after the lead pipe was removed C. was given a course of potassium iodide, and lead was found in his urine.

At present he bears exertion a little better, but his heart is still enlarged, and his arteries still thick and

* Read at the Annual Meeting of The Massachusetts Medical Society, June 12, 1907.

hard. He has never before had any serious sickness, and comes of a long-lived family.

Mrs. C., thirty-seven years of age, wife of G. H. C., a pale, thin, and delicate looking woman, after living a year and a half in Littleton, began to be troubled by obstinate constipation; the bowels could be moved only by powerful cathartics or enemata; the colon could be felt through the thin abdominal wall like a solid cord. At times the introduction of an enema was impossible, except under the influence of a dose of morphine. The evacuation at such times consisted of small, hard lumps of feces, with much mucus in shreds and strings.

I made a diagnosis of mucous colic, and prescribed a coarse vegetable diet, as recommended by Von Noorden. The patient held to this diet faithfully for several months, with great relief. At this time I flattered myself upon the acuteness of my diagnosis, and the successful treatment of the case.

A year later, in the fall of 1905, Mrs. C.'s abdominal trouble returned with great severity. There were intense colic, constipation, slow pulse, flat abdomen, a distinct lead line on the gums and the discovery of lead in the household water supply. The mucous colic had become plain lead colic; the usual treatment of lead poisoning brought complete relief; Mrs. C. is now well with gain of flesh and ruddy color, and has had no return of the colic, either mucous or lead.

Mrs. G., mother of Mrs. G. H. C., suffered from a persistent and debilitating diarrhea, for two and a half years from the time of moving to Littleton with her daughter, until lead was eliminated from the family water supply, when she recovered, and has been free from diarrhea for the last year and a half.

T. G., seventy-eight years of age, has lived in a farm house in Harvard, Mass., since 1899. The house was then supplied by water drawn from a well through 275 feet of lead pipe. Two years later, in the spring of 1901, his right hand, right leg, left hand and left leg, in the order named, became weakened to such an extent that he was confined to his bed. At the same time he suffered severe but intermittent abdominal pain. The abdominal symptoms and the weakness of his arms and legs became steadily worse, until September, four months in all, when the extensor muscles of both hands and both feet were paralyzed. His abdomen was hard and tender. There was a prominent lead line on his gums. The family was then supplied with water known to be free from lead. He made a tedious and partial recovery. At present, six years after his lead poisoning, his grasps are good, he opens his hands partially and feebly only. He walks with some difficulty, and falls if his knees happen to become much bent. The extensor muscles of his forearms, thighs and legs are wasted and weak. He says he feels well. He has a ruddy complexion, soft peripheral arteries and a normal urine.

J. M., forty-seven years of age, has lived for the last ten years on his farm near West Acton, Mass. Seven years ago he had a serious sickness accompanied by great pain in the abdomen, for which he was treated at the Massachusetts General Hospital where he was told that lead poisoning was the cause of his trouble. He has had a similar sickness every summer since.

I was first called to him in the summer of 1905, for a well marked lead colic, in which he had great pain, constipation, slow pulse, with wakeful and delirious nights. His skin was of a muddy pallor, his hair very gray, his radial and temporal arteries tortuous and hard. There was a plain lead line on his gums.

The family was supplied with water brought from a spring in milk cans. Projecting into this spring was a piece of lead pipe, once used for pumping water into the house. A little probing with a slender stick showed that the water entering the spring came in alongside the lead pipe, after flowing a considerable but uncertain distance in contact with it. There was ample chance for solution of lead from the outside of an old pipe. J. M. was told that this lead pipe was the cause of his sickness, and he was advised to remove it.

A year later, in the summer of 1906, I was called to him again, because of a repetition of his colic, and found the lead pipe still in the spring. He was advised again to take it out. About a month after, he was attacked once more with colic, and the pipe had not been removed. I then told him that he must put away the lead pipe or get another doctor, and he finally got rid of the pipe. Lead was found in his urine at this time. His health has improved, but he is still far from well. After ten years of lead poisoning, at the age of forty-seven years, he looks, talks and acts like an old man.

Mrs. P., eighty-four years of age, has lived for about fifty years in a house in Shirley, Mass. For many years (forty or more) she has been partly crippled with what she called rheumatism. She was not able to walk outside of her house for years on account of lameness of her knee, ankle and toe joints. Her hands were nearly useless. The wrist and knuckle joints especially were swollen and deformed. All these joints were painful and tender, the pain being much worse at night. Many kinds of treatment had been tried without benefit, several at my suggestion. The water supply at this house has always been spring water pumped a long distance through lead pipe. It has been examined and lead was found in it. Two years ago, at my suggestion, water was taken from the public supply through an iron pipe, and the spring water was stopped. Since the change, and with no other treatment, Mrs. P. has lost her rheumatism entirely. She walks with ease and comfort. Her wrist and finger joints are free from swelling and she uses them with much facility.

Mrs. J. E., sixty-four years of age, consulted me in 1897 for "sciatica." There was also a history of rheumatism affecting the joints of the hands, with a long continued, painful affection of one shoulder and arm, the pain being worse at night.

The water supply of the family was drawn through many rods of lead pipe. Lead was found in the water and in the patient's urine. Iron pipe was substituted for lead. Mrs. E. recovered completely and has been free from rheumatism for the last ten years.

Mrs. M. has lived on her farm in Harvard, Mass., forty-seven years. Water for her house comes from a spring, through lead pipe, and contains a dangerous quantity of lead. She has suffered for many years with what she calls rheumatism. Her finger and wrist joints are enlarged and distorted. She suffers pain and lameness in all her extremities. Her health in other respects seems good. Her color is good.

Nellie M., forty-three years of age, daughter of Mrs. M., has always lived at home. She is pale and cachectic in appearence, looking much older than her years. She began to have pains in the extremities, which she calls rheumatism, about twenty years ago. Her left leg and thigh were first affected. Lameness was troublesome, and pain was severe at times. For the last seven years she has suffered much pain in the left shoulder, arm, forearm and hand, worse at night. The left hand trembles with a moderately coarse tremor. She suffers from frequent and severe headaches. These people have been warned many times in the last few years that their water supply is dangerous, but they continue to drink the lead water and suffer the pains.

W. K., fifty-seven years of age, has lived on his farm in Harvard, Mass., eighteen years. During the last five years he has had sciatica, brachial neuritis, and

many other painful ailments of an indefinite nature. In March of this year he was seized with severe headache which lasted for two weeks. He has the appearance of a very old man; his heart is enlarged; his radial and temporal arteries are thickened and hard. His house is supplied with water from a spring, through lead pipe. The pipe corrodes so much that it leaks and requires repair several times each year. The water at the house contains considerable lead. K.'s urine contains a large trace of lead.

Mrs. K., fifty-one years of age, wife of W. K., looks much older. Her hair is completely white. Her skin is of a grayish pallor.

In the spring of 1906 she had a severe brachial neuritis. A year later she suffered from a sharp attack of lead colic. K. has been warned of the danger of lead poisoning by Dr. Royal, of Harvard, and myself many times during the last few years, but he has only lately become a believer and turned from drinking lead water.

A. S., fifty-four years of age, first consulted me in 1904, on account of a troublesome vertigo. His heart was enlarged; his peripheral arteries thickened and tortuous; he had a pulse of high tension and the urine of chronic interstitial nephritis. Lead was found in his urine. For ten years he had been using rain water stored in a cistern with distributing pipes of lead. A year later, in 1905, a progressive cerebral degeneration appeared in S., and he died in the summer of 1906.

Mrs. S., Harvard, Mass., in middle life, consulted me several years ago because of recurring pain in the abdomen. She had a plain blue line on the gums and was using water brought to her house through lead pipe. I warned Mrs. S. and her husband of the danger of using the contaminated water, but they were skeptical and clung to the lead pipe. Dr. Royal, of Harvard, tells me that Mrs. S, has suffered several attacks of brachial neuritis in the last few years, and that he has had the water at her house examined for lead, with a positive result. In spite of these warnings they refuse to abandon the lead pipe.

Mrs. R., forty-six years of age, has lived for ten years in a tenement house in Shirley, Mass. She suffers greatly with neuralgic attacks, affecting at various times the head, face, both brachial regions and the right crural region. Such treatment as she has received has been of little use. Her house is supplied with spring water carried in lead pipe. Examination of this water for lead is positive.

Mrs. C., seventy years of age, has lived in a cottage house in Harvard, Mass., since 1891. During much of that time she has been greatly troubled with "rheumatism." In the autumn of 1903 she had several attacks of angina pectoris. She was very pale, with swollen ankles and the urine of a chronic nephritis of moderate degree. The family used water drawn from a well through lead pipe. Examination of the water for lead gave positive result, and its use was stopped. Mrs. C. passed a poor winter with much cardiac distress and edema of the legs. In the spring of 1904 she got some relief and has gradually improved since. She now has the urine of chronic interstitial nephritis, with a pulse of high tension and good cardiac compensation. Her life is tolerable.

George H. C., seventy years of age, husband of Mrs. C., lived in the house now occupied by them from 1850 to 1863, and from 1891 to the present time. He has been the victim of dreadful headaches for many years (forty or more). At the time of the discovery of lead in C.'s well water (1903), he was pale and emaciated and suffered frequently from severe headaches, lasting several days at a time. Since the lead water was stopped he has improved greatly in health. He has lost his headaches, has a ruddy color and has put on much flesh.

From 1894 to 1903 Mr. and Mrs. C. passed several winters in California, being much pleased with the effect of the change of climate upon themselves, he always losing his neuralgia and she her rheumatism in California, only to find them again in Massachusetts. Since stopping the lead water they have been as free from these ills in Massachusetts as in California.

Mrs. C., mother of G. H. C., lived in the same house with the same water supply, from 1850 until her death in 1880 at the age of eighty-two years. In 1855 she began to be troubled with "rheumatism," which gradually increased, affecting the hands and feet chiefly. She was completely crippled for the last thirteen years of her life, having comfortable days and intolerable nights.

CONCLUSION.

This group of cases is but another illustration of the many forms in which lead poisoning makes its appearance, and the various kinds of damage done by it.

The acute cases are few; the chronic painful and disabling affections and arteriosclerosis, with the things that go in its train, are in the majority.

My own experience is one of failure for years to recognize lead poisoning as a frequent cause of many of the painful and disabling ills that I have been called upon to treat. I recall many instances of vague abdominal troubles, and of painful and crippling affections of the extremities which the patient called rheumatism, and for which I had no better name, that I tried vainly to relieve, and which may well have been due to poisoning by lead.

Other physicians may have failed to recognize lead poisoning as I have done. Many people look upon what they call rheumatism as something to be endured without hope of relief, and the cause of their ailment is never discovered. Arteriosclerosis comes on insidiously, until some terminal accident occurs, and lead as a possible cause is rarely thought of. It seems fair to assume, therefore, that my cases are but a fraction of those occurring in the same locality, the whole making a heavy burden of pain and disability upon the community.

The use of lead pipe for carrying water is common throughout the whole of rural New England. The mischievous quality of dissolving lead differs, no doubt, in the waters of different localities and at different times. But I believe such use of lead is always and everywhere dangerous, and that the possibility of serious poisoning ought to be more generally recognized than it now is.

Boston City Hospital.

CLINICAL MEETINGS OF THE STAFF, MARCH 21 AND APRIL 18, 1907.

LIPOMA OF THE EPIGLOTTIS.

BY T. A. DE BLOIS, M.D.

If you will look over my right shoulder by the aid of the transillumination lamp, furnished by the better current tap, I will show you three out of my five cases which have come up to-night. First is Mrs. L. B., a patient in the Throat Department, absolutely without

previous history, as regards syphilis, tuberculosis, carcinoma, etc. . . . You will observe on the left margin of the epiglottis a whitish mass. This swelling is easily compressed, is without pain and is apparently a cyst of the epiglottis. I only saw it for the first time to-day. Some day I will cut it, or perhaps, on account of its juxtaposition to the larynx, I will aspirate it.

(Meeting of Thursday, April 18.) I would like to add a few words about the case which I reported a month ago, as a cyst of the epiglottis. Yesterday I again saw this case; it had enlarged very much; it had not ruptured spontaneously as I thought it might; it easily compressed under pressure with the probe; there evidently was no fluid there. Besides this, the tumor had become nodulated. From gross appearances, I should say this was not a cyst, but a fatty tumor, "lipoma." It might, of course, prove malignant; modulated tumors frequently are. Fatty tumors of the air passages are not so rare. I have reported one; Dr. Farlow reported two; some unknown Italian, with questionable veracity, reported thirty. My second case, Miss O. K., has tuberculosis of the larynx. You will see the little yellow masses of tubercular deposit on the epiglottis. By and by it will break down. But what is much more important is the tubercular ulceration of the pillar of the fauces. This is rare. Of course, the prognosis is of the worst.

My third case, Mr. X. L., has tuberculosis of the larynx. He presents the peculiarity of having both the pyriform swelling of the arytenoids and the interarytenoid proliferation of tuberculosis. This will so affect him that he will lose the power of swallowing solid food much earlier than if he had the single lesion either on the interarytenoid space or else on the arytenoids; either one of these is rapidly fatal. But perhaps my friend, Dr. Leland, can give a more hopeful outlook from his varied experience.

I. A CASE OF SLOW-GROWING ANEURISM OF THE AORTIC ARCH. II. PONTINE HEMORRHAGE. III. ANEURISM OF BOTH CAROTIDS. IV. PROFOUND ANEMIA AND PURPURA. V. A CASE OF CARCINOMA INVOLVING THE THYROID GLAND. VI. A CASE OF ACUTE RHEUMATISM WITH MIXED ERYTHEMATOUS AND PURPURIC ERUPTIONS.

BY CHARLES F. WITHINGTON, M.D.

I. This case is interesting, among other reasons, for the fact that we had the patient under observation in this hospital nearly a year ago and have the records and measurements, as well as x-ray plates, to show the progress of the disease in the last twelve months.

The patient is a man of forty-four years. He denies venereal disease. About eighteen months ago he began to have dyspnea and some regurgitation of solid food soon after swallowing it. No pericardial pain; no edema. He entered my service April 1, 1906. There was at that time asthmatic breathing. The right side of the heart was 2 cm. from the parasternal line; above at the level of the second rib, the dullness swung out to 5 cm. from the median line. At the same level dullness extended equally far to the left. There was a tracheal tug and a thrill. The radiograph showed a shadow corresponding to the percussion dullness.

After leaving the hospital he had dyspnea and some regurgitation of food. He felt as if bread and other solids "stuck" in his gullet.

He has recently re-entered the hospital, and the present x-ray plate shows the transverse measure of the aneurism to be about 1½ cm. greater than a year ago. The growth has been to his left, corresponding to the descending portion of the arch. His dysphagia is very marked for everything but liquids. There is a tracheal tug and the right radial pulse is slightly in advance of the left. There is no laryngeal paralysis. There is cough and auscultation; shows an almost complete absence of breathing throughout the left lung; at the same time there is perfectly good resonance all over this lung. This combination, where one can exclude pneumo-thorax, is practically conclusive of obstruction of a primary bronchus. We may then believe that this man has from his slowly growing aneurism, two marked pressures, one on his esophagus and one on his left primary bronchus. While unable to work, he is reasonably comfortable.

II. The specimen shown came from a man of fifty-five, who fell unconscious while at his work, never spoke or moved again and died in three or four hours. There was no localized paralysis, but a slight spasticity of arms and legs. There was a Palinski reaction on the left side.

The specimen shows numerous white plaques throughout the basal vessels. There is a hemorrhage in the center of the pons, with fluid blood and clot and an area of softening about 2½ cm. wide surrounding the clot.

III. The patient is a colored woman, aged nineteen, single. She has a history indicating probable syphilis and there is a diffuse macular eruption over the trunk. She has had several attacks of rheumatism during the last eleven months, with dyspnea and cough. For the last seven months the abdomen has been distended, and two months ago it was tapped and a large amount of clear fluid withdrawn.

She has a dilated heart, 2½ cm. to right, and 13 cm. to left of median line, with a loud systolic murmur at the apex and both systolic and diastolic murmurs at the ensiform. The liver is distinctly palpable through a thin layer of fluid and its edge, smooth and hard, is felt at the navel. There is considerable ascites and fluid in both sides of the back, from the angle of the scapula down, but no edema of the legs.

There is fusiform aneurism, seemingly 1½ inches or more in diameter, involving the right common carotid from the level of the clavicle to the angle of the jaw. It is markedly expansile and shows a murmur and a thrill, both corresponding with systole. The jugular vein pulsates over it.

The left common carotid shows a less advanced stage of the same pulsation. The pulsation is very strong, covering about the same length as the right aneurism, but the breadth is not much over ½ or ¾ inch.

No other peripheral vessels appear to be affected.

The case seems inoperable at present, because, first, of its multiple localization, and, secondly, because of the marked involvement of the heart itself. It is well known that cardiac enlargement is not produced by aneurism alone, even of the aortic arch, and the evident dilatation which we have here indicated so marked a degree of valvular and myocardial trouble as to forbid operation for the aneurism.

IV. This patient has profound anemia and purpura,[1] of rapidly progressive development. The patient, a vigorous Italian laborer of twenty-one, has complained for only two weeks of severe headache and sudden loss of sight in one eye. For the last few days he has been bleeding from the gums, and the blindness of the right eye proves to be due to a large retinal hemorrhage. For the last two days purpuric spots have been appearing on the left arm and the belly. The spleen is not enlarged and there are no enlarged lymph nodes.

The only blood examination yet made shows hemo-

[1] This case, which proved to be one of aplastic anemia, is reserved for fuller publication later, together with post-mortem findings.

globin 35%, reds 1,2000,000, whites 3,500. There is achromia and marked poikilocytosis, but no nucleated reds are found. A differential count of the white corpuscles gives polynuclears 12%, large lymphocytes 22%, small lymphocytes 66%. No eosinophiles. In the three days that the boy has been under observation, he has been rapidly losing ground.

V. The patient, a woman of thirty-seven, says that up to six weeks before entrance, she was well. At that time her throat began to swell and there was difficulty of speaking, with cough, dyspnea and great prostration. The most obvious thing about her at entrance was a greatly enlarged thyroid gland substantially as it is to-day. The enlargement is uniform, involving both the lobes. On the outer side of this on either side is a greatly enlarged lymph gland, the larger being on the right; both have increased rapidly since she entered the hospital. There is no exophthalmus nor Stelwag nor von Graefe's sign. No tumor. The heart is rapid, regular, full, without murmurs.

There is, as you see, great hoarseness and a crowing respiration, suggesting croup. A laryngological examination shows a tumor of the right arytenoid, encroaching on the glottis, which the throat department say is malignant. These extrinsic carcinomata of the larynx are particularly rapid of growth. The lymph node on the side of the tumor is the larger of the two. The propinquity of the thyroid to this growth makes it probable that the tumor of that organ is also a carcinoma, secondary to that of the arytenoid.

There is a slight dullness extending down the sternum and a little to either side of it, as far as the heart. This x-ray picture shows a shadow corresponding to this dull area, which is believed to be due to secondary involvement of mediastinal glands.

The liver is much enlarged and its lower edge, below the navel, is markedly lobular, one especially distinct lump, as big as a lemon, being felt at the outer edge. No axillary or inguinal glands are felt to be enlarged. The great dyspnea of the patient suggests the possibility of a sudden choking. In that case, intubation would be impossible, owing to the site of the primary growth and trachiotomy would be exceedingly difficult by reason of the great size of the thyroid. (The patient died, fortunately without asphyxiating.)

VI. The patient, a girl of twenty, had an attack of rheumatism, several years ago, without skin manifestations.

The present attack is one of acute joint inflammation, with loud presystolic and systolic mitral murmurs. From the beginning she has had a copious skin eruption, which, when first seen, was of a pale red color, not raised above the surface, not painful. The spots are very thick, especially on the back legs and buttocks, and took at first marked circular forms; gradually dark purpuric spots became mixed with them and finally the eruption became wholly purpuric. The case is of interest as showing the relations of both forms of skin eruption with rheumatism. Osler and several other writers have called attention to the interchangeability not only of the two eruptions, which we have here, but also of these with urticaria and angioneurotic odema. The patient has none of the gastro-intestinal symptoms which may accompany the erythemata and which often accompany the purpurias, urticarias and angioneurotic edemas.

I. A CASE OF OBSTETRICAL PARALYSIS IN A BABY EIGHT DAYS OLD. II. POST-DIPHTHERITIC INTESTINAL PARESIS.

BY C. M. GREEN, M.D.

I. The mother of the patient was admitted the day after delivery, suffering with pneumonia, from which she died four days later. Delivery was reported to have been effected with low forceps. The baby was well developed, weighing 8.25 lb. and had a cephalhematoma in the region of the posterior fontanelle; the left arm was completely paralyzed. The x-ray disclosed no gross lesions.

Many of these cases recover under the long use of massage, passive motion and, perhaps, electricity, with attention to general nutrition and the prevention of local atrophic changes from disuse. In the more serious and in the neglected cases, surgery now promises at least partial relief. Attention is called to a paper of Dr. Alfred S. Turner, of New York, on "Results from the Surgical Treatment of Brachial Birth Palsy," which appeared in the *Journal of the American Medical Association* for Jan. 12, 1907.

II. The patient is a young woman, with abdominal pain and distention, dullness in the flanks, and obstinate constipation. Five years before, in another hospital, an exploratory laparotomy was performed on account of abdominal pain; but nothing found to explain this symptom. The patient now declines to take ether, and without anesthesia nothing had been found to account for the symptoms, except the obvious intestinal paralysis. It would seem that this atony of the bowel is adequately explained by the history.

The woman was in the South Department in July, 1906, suffering with diphtheria. Seventeen days after entrance she began to have loss of power in hands and legs; she also had paralysis of the muscles of deglutition, and regurgitated liquids through the nose. At this time also she began to be troubled with constipation. Seven weeks later she was transferred to the Second Medical Service, where she was treated for four weeks for abdominal distention and constipation. She then passed four weeks in the Convalescent Home, whence she was sent back to the hospital and re-admitted to the Second Medical Service; the abdominal distention and constipation had grown worse. Here she remained three months; there was still some loss of power in hands and legs, but the paralysis of the muscles of deglutition had disappeared.

The case as now seen appears to be one of post-diphtheritic intestinal paralysis, and under treatment with high turpentine enemata, the distention has considerably diminished and the symptoms are somewhat relieved.

I. OCULAR INJURIES FROM DYNAMITE EXPLOSIONS. II. SYMPATHETIC OPHTHALMIA. III. CONJUNCTIVAL GRAFT FOR CORNEAL ULCER.

BY ALLEN GREENWOOD, M.D.

I. Three cases of ocular dynamite injuries, showing varying degrees of severity. The first case was injured Jan. 10, 1907, and now shows in the right eye a healed puncture wound of the sclera, just to the nasal side of the ciliary region, with good resulting vision. The left eye shows a fair vision after the removal of the traumatic cataract, which resulted from perforation of cornea and lens. The cataract was removed by suction and irrigation.

The second man was injured Jan. 22, 1907, and shows the left eye destroyed and shrunken. The right eye shows a central leucoma adherens, with light perception. In this eye an iridectomy may later restore some vision.

The third man was injured Feb. 18, 1907, and shows such extensive lacerations of both eyes that phthisis bulbi is the expected outcome, with complete and permanent blindness. These men, all Italian laborers,

were injured by driving the point of their picks into an unexploded dynamite cartridge.

II. This patient has been struck by flying glass, resulting in perforating injuries to both eyeballs. In both the injury involved the ciliary region. He entered the hospital Dec. 16, 1906, and was discharged Dec. 27, with both eyes quiet and having good vision. He was re-admitted Feb. 7, 1907, with both eyes showing a moderate irido-cyclitis, and it was found impossible to tell which eye was the offending one and which the sympathizing one. Both are improving under mydriatics, heavy doses of salicylates and inunctions of Hg.

III. A woman of forty was shown, who had developed three months before a progressive ulcer of the lower corneal margin. This had increased in spite of all treatment, until it involved one third of the circumference of the cornea and was about 4 mm. wide and half through the thickness of the cornea. A week before showing her, the ulcer had been curetted under ether and a flap of conjunctiva transplanted, so as to cover the whole of the ulcerated area. This conjunctival graft has become firmly attached to the previously denuded corneal area, and the eye is quiet and comfortable.

A CASE OF PERFORATION OF THE INTESTINE IN TYPHOID FEVER. OPERATION. RECOVERY.

BY F. B. LUND, M.D.

WM. A. L., aged thirty, was admitted to the service of Dr. John L. Ames, on Oct. 31, 1906. He had been ill at his home for four weeks, suffering chiefly from headache and vomiting. On entrance he had a temperature only slightly above normal, presented rose spots and was believed to be in the fourth week of a typhoid and beginning to convalesce.

During the night of Nov. 1, he had slight abdominal pain, so slight, however, that he did not summon the orderly on duty. At about 8 A. M., on Nov. 2, he was suddenly seized with very severe abdominal pain, he was seen by Dr. Ames at about nine, who found normal temperature, pulse 120, but of good quality, very marked muscular spasm and tenderness over the whole abdomen, especially marked in the right iliac region. The writer saw him in consultation with Dr. Ames about 9.30 A.M., which was within two hours of the time of the perforation. The diagnosis seemed plain, and on the patient's being informed that his bowel had sprung a leak, he was too only glad to let us try to close it.

Under ether an incision four inches long was made around the border of the right rectus. The cecum, which lay just beneath the incision, was found to be thick and reddened, having fibrin flakes upon its surface, but inspection disclosed no perforation. The lowest coil of the ileum, which is the best probable seat of perforation, was then found by running the forefinger around and beneath the cecum and hooking it up close to the ileo-cecal junction; the marked inflammation of this coil made it evident that the perforation was close by, and on looking at the under side a small plug of feces was seen projecting from a pinhole perforation. The wall of intestine about the ulcer was thick and stiff from inflammatory infiltration, but the ulcer was closed by two layers of continuous inverting sutures of catgut. The purulent and fecal contents of the pelvis were washed out with salt solution, and the entire abdomen was washed out, as the intestines, as far as could be seen, were all acutely inflamed. A cigarette drain, with a large rubber tube in the middle, was carried to the bottom of the pelvis, through the lower angle of the wound, and the remainder of the incision closed by through-and-through sutures of silkworm gut. The drain was so placed that in case the suture should give way, the leak would take place into its track. This proved a valuable safeguard three or four days later, when a fecal fistula became established. The patient was put to bed in a sitting position and so remained during convalescence. The temperature was normal after the operation and remained so. Infection of the wound resulted in some sloughing of the aponeurosis, and even in hemorrhage from the deep epigastric artery, but recovery was finally complete.

I. CASE OF BENIGN INDURATED ULCER OF THE PYLORUS SIMULATING MALIGNANCY OF OPERATION. EXCISION OF THE PYLORUS. DIVISION AND RE-SUPPLANTATION OF COMMON BILE DUCT. RECOVERY. II. CASE OF PYLORIC OBSTRUCTION DUE TO ULCER SCAR AND ADHESIONS. POSTERIOR GASTRO-ENTEROSTOMY. RECOVERY.

BY FRANKLIN W. WHITE, M.D.,
AND
F. B. LUND, M.D.

I. The patient, a carpenter, aged fifty, was first seen by Dr. White, on Nov. 7, 1906. He had had ocasional intervals of indigestion for the last twelve years. In the last six months the disturbance had been continuous and severe. His mother died of cancer of the breast. Previously used tobacco and beer to excess. His earlier trouble consisted of epigastric distress and soreness, both before and after meals, usually increased by eating. Much gas on stomach, occasional vomiting, constipation, no loss of weight. No history could be obtained, which definitely indicated a previous ulcer. His best weight was 150 lb. at the age of twenty-five.

In the last six months his digestive trouble has been more severe and steadily increased. He has had nausea and distress and pain in the epigastrium, coming usually after a meal, or in the night, relieved by copious vomiting, sometimes of one or two quarts of some liquid containing undigested food. His appetite was good and he was more thirsty than usual. In spite of some excess of liquids taken, he passed only 800–900 cc. of urine daily. This is explained by the frequent vomiting and the lessened amount of liquids which were able to pass the pylorus and reach the bowel, where absorption chiefly occurs. He was much troubled by eructations of gas and distress of the stomach. He was habitually constipated. He had lost between 10 and 15 lb. in the last six months and weighed 126 lb. at his first visit.

Patient was well developed, rather thin and pale. Nothing abnormal found in any organ except the stomach. The history so strongly suggested gastric stasis that a Boas test supper (cold meat, bread and butter, large cup of tea) was ordered and the patient reported fasting next morning. Fifteen hours after the test supper 150 cc. of residue was found in the stomach, containing large particles of undigested food. Free HCl, 16. Total acidity, 22. No lactic acid. Microscopic examination showed very abundant actively growing sarcinæ and yeast cells.

The lower border of the stomach on inflation was 2 or 3 cm. below the navel. No splashing was heard over the fasting stomach and there was no visible peristalsis.

Examination of the stools for blood by means of the guaiac test gave negative results.

The diagnosis of benign pyloric obstruction was made and treatment was begun by means of appropriate diet and stomach washing. Lavage was performed

daily at first, then two or three times a week. There promptly followed a marked lessening of distress and vomiting, and the patient gained 7 lb. in two weeks' time. The patient gained in strength, and the amount of urine increased to 1,000 cc. and the amount of residue in the fasting stomach was reduced to 60 cc. It was impossible, however, to get the stomach to entirely empty itself, even after the course of lavage and little setbacks, such as distress and vomiting occasionally occurring with slight indiscretions in diet, and as patient's circumstances made it difficult for him to carry out the treatment, and the medical treatment seemed likely to be very prolonged and the result incomplete, Dr. F. B. Lund was asked to see the patient. Operation was agreed upon, with a diagnosis of benign pyloric stenosis, and the expectation of performing a gastro-enterostomy for the relief of the mechanical obstruction.

The patient was operated upon Nov. 28, 1906, by Dr. Lund. A median epigastric incision showed marked dilatation of the stomach with hypertrophy of the pyloric group of glands on both the greater and lesser curvature, marked induration and thickening of the pylorus, apparently extending along the posterior wall as far as the beginning of the second portion of the duodenum. The condition had every appearance of carcinoma, and resection was decided upon, in spite of the extent of the duodenal involvement. The long clamps were placed so as to remove the pyloric third of the stomach, and after ligating the gastric and gastro-epiploic arteries, the gastro-hepatic and great omentum were divided, the stomach divided, the mucous membrane cauterized and the dissection carried on between the pylorus and the pancreas. The tumor was found firmly adherent here, and in separating the adhesions the portal vein was exposed and a small branch ligated close to it. In the first portion of the doudenum the common bile duct was found to have been divided, presenting as a thick muscular tube, with the bile coming from its end. It was divided behind the first portion of the duodenum. The duodenum was cut across at the junction of the first and second portions, the mucous membrane cauterized and the upper end inverted. A small slit was then made in the inner side of the duodenum. Three No. 1 catgut sutures with the needles in were tied into the end of the common duct, and the needles carried into the duodenum, through the opening made to puncture the wall at about one inch below the opening and one-quarter inch from one another. The threads were then drawn taut and tied, thus anchoring the duct in the duodenum. At the point of the entrance of the duct into the duodenum the former was sutured in the opening by four fine catgut sutures. Cholecystostomy was then performed, in order to relieve the junction of the flow of bile for a time. Posterior gastro-enterostomy was performed, uniting the first loop of the jejunum to the remainder of the stomach. A Murphy button was employed in order to save time. A gauze drain was carried down to the eroded surface of the pancreas, on account of slight oozing there, and the abdominal wound sutured. The patient bore the operation well and the next day was in fine condition. On removal of the gauze drain on the sixth day, there was a serious discharge, which persisted for several weeks. Examination showed the presence in it of neither gastric nor pancreatic ferments. The bile was discharged through the gall bladder for eight days. Then, on removal of the tube, the external discharge ceased almost immediately. At no time did bile disappear from the stools. The patient made a gradual recovery and left the hospital well on Jan. 18, 1907, weighing 136 lb. On Feb. 14, 1907, his weight was the same and his condition good.

The diagnosis, the results of medical treatment, the unusual operation, the simulation of malignancy at operation and the result are the features of interest in this case.

The diagnosis of gastric dilatation and stasis of food in the stomach was easy. The cause of the dilatation required further study. The story of the trouble was not the typical short history of cancer, with rapid loss of weight, and on the other hand, no history was obtained of a previous gastric ulcer, nor of inflammation about the gall bladder, which might cause adhesions. It is interesting to note how frequently the end results of gastric ulcer are found without any clear history of the original attack.

The presence of considerable free HCl in the fasting stomach showed that gastric secretion was good, though the amount of secretion resulting from irritation of the stagnating masses of food upon the gastric gland is often much greater in benign stenosis, giving a total acidity of 100 or over, due to HCl and acid products of fermentation. The presence of HCl in the fasting stomach and an acid fermentation due to yeast and sarcinæ is the rule in benign pyloric obstruction, due to ulcer scar adhesions and the like, and the exception in well developed gastric cancer. Out of 48 cases of gastric cancer seen by Dr. White, and in which careful records of stomach analysis were kept, there were 6 cases in which free HCl was found in the stomach contents, even after the disease was well developed. With one exception, these were proved to be cases in which the cancer developed upon an ulcer base. This observation that about one case in eight of well developed cancer of the stomach may have free HCl in the stomach contents agrees with the conclusions of Boas, Ewald and others, from a much greater experience.

In order to determine whether or not we were dealing with one of these exceptional cases of cancer, the stools were examined for traces of blood, after putting the patient for two days on a diet free from meat, fish and extracts. It has been shown that in well developed cancer of the stomach traces of blood are found with great constancy in the stools. Such examination of the stools should not be made until two days after the passage of a stomach tube to avoid confusing a spontaneous hemorrhage with a trace of blood possibly caused by intubation.

The diagnosis of benign pyloric obstruction was made, and since every case of gastric stasis represents a stomach in a stage of failing compensation, we attempted to restore this compensation by means of diet and lavage. The dietary treatment consisted in restricting liquids and giving five small meals a day to avoid distention of the stomach, and the use of brothy and pasty food, which could easily pass the pylorus, and rich in fat, so that it might contain sufficient calories. A good rule is to give food which will easily pass through a rather fine sieve (cream, butter, sweet oil, milk, gruels, raw egg, beef juice, meat, jellies, vegetables, purées, apple sauce, etc.).

Lavage of the fasting stomach was followed by the introduction of 100 cc. of warm sweet oil, which served the purpose of lessening pyloric spasm, of combating the hyperacidity and of increasing nutrition.

The good results of this treatment were seen promptly in a marked lessening of distress and vomiting, a gain in weight from 126 to 133 lb. within two weeks. The limitations of the treatment are also seen in the fact that it was not possible by means of it to get the stomach to empty itself completely. It is always desirable to faithfully carry out medical treatment in all cases of benign pyloric stenosis before resorting to operation, for two reasons. In some of the milder cases, especially those in which the elements of pyloric spasm is prominent, medical treatment may be all that is necessary. In the severer cases, it is often of great service in improving the general condition and thus preparing the patient for operation.

Simulation of malignancy in lesions or secondary glands may prove disturbing and subject the patient to a long, elaborate operation, when a shorter and simpler one would otherwise have been chosen. Examination of frozen section of doubtful tissue, by a pathologist, during the operation, may be of service, but even this is not always sure. This is the second case within a short time in this city, in the knowledge of the writers, when a benign condition of the stomach has been diagnosed and treated as malignant disease at operation. The immediate results in both cases were good, however.

II. The patient, a coachman, aged forty, was first seen by Dr. White, on Jan. 1, 1907. He has had stomach trouble for a year, which has become gradually worse. His family history is good and he remembers no previous illness, except measles in childhood. He has used beer and whiskey moderately and no tobacco. During the last year he was troubled with heartburn, epigastric distress or pain and nausea coming usually several hours after a meal and relieved by vomiting. The attacks of vomiting occurred at first at intervals of several weeks, became gradually more frequent and troublesome and now are of almost daily occurrence and often several times a day. The vomitus was described as watery and sour, sometimes containing lumps of food and recently as much as a quart in amount. Vomiting frequently occurred between 10 P.M. and morning, at a time when the stomach should normally be empty. He described his vomitus and stools as "black" on several occasions. He had much eructation of gas. His appetite was good at first, but recently poor and he was afraid to eat. His diet was formerly generous, but now consisted chiefly of milk, of which he took two quarts a day. He was very constipated, has lost much sleep and become very weak and short of breath. He had spent most of the time in bed for two weeks previous to seeing Dr. White. His weight a year previous was 145 lb. and on Jan. 1, 99 lb. He had sought medical advice several times in the last six months, but without improvement. He was referred to Dr. White as a case of cancer of the stomach, probably hopeless and too late for operation, and he certainly looked the part.

He was greatly emaciated, pale and weak. Nothing else abnormal was found outside the digestive tract. His teeth were good. The abdominal walls were very thin and lax. Splashing was obtained over a large area, extending two or three inches below the navel, and waves of peristalsis were seen passing over the greater part of the abdomen from left to right. On inflation the stomach was found to be greatly dilated and the lower border half way between the navel and pubes. The liver edge could be distinctly felt and was hard and slightly uneven.

The patient had eaten no breakfast on the morning of the first visit and only a very slight supper sixteen hours previous. A stomach tube was passed and 1,000 cc. of sour liquid, containing much food residue, was withdrawn, which foamed like beer and had the characteristic "sour bread" odor of the fermentation, due to sarcina and yeast. Free HCl, 40; total acidity, 89. Microscopic examination showed enormous quantities of sarcinæ and branching yeast plants.

The diagnosis of pyloric obstruction, probably of benign nature, was made and the treatment begun by appropriate diet and gastric lavage, with the object of cleaning up the stomach and improving the patient's condition before operation. Rectal enemata of water were given to relieve thirst. No great improvement was expected or obtained through medical treatment. The fasting stomach residue due to hypersecretion and stasis of food was never less than 600 cc. and was similar in character to that obtained on the first visit, always containing an abundance of free HCl and showing marked signs of fermentation. The guaiac test for blood was twice positive and twice negative in the stomach contents. The guaiac test for blood in the feces on a meat-free diet was once positive and three times negative.

Dr. F. B. Lund was asked to see the patient a week later and operation agreed upon. This was performed by Dr. Lund on Jan. 7. Through a right rectus incision a posterior gastro-enterostomy was done with the short loop according to Mayo's method. The pylorus and pyloric portion of the lesser curvature were greatly indurated and caught up to the under surface of the left lobe of the liver by adhesions exactly in the median line. The stomach was enormously dilated, and extended below the umbilicus on the left side of the body. Convalescence was complicated by a cough, and on the twelfth day after the removal of the stitches a loop of intestine was coughed out through the incision which required resuture.

The patient did not vomit after the operation, has gained steadily in weight and has practically no symptoms of digestive trouble.

The most interesting features of this case were the diagnosis and the result of operation.

The history of "black" vomitus and stools, the extreme emaciation and obvious pyloric obstruction suggested cancer of the stomach, but the invariable presence of plenty of HCl in the stomach contents made benign obstruction much more probable. The examination of the stomach contents and feces for blood were of much help in ruling out an exceptional cancer with good HCl secretion. The test was negative two out of four times in the stomach contents and three out of four times in the feces. These negative results are strong evidence against cancer, in which *constant* positive results are almost invariably found in a well developed case. *Occasional* positive results are not uncommon in marked cases of benign pyloric stenosis, as has been shown by Boas, Hartmann and White; the traces of blood are probably due to small erosions

or capillary hemorrhages, resulting from stasis and irritation of the mucosa.

It seems unfortunate that this patient should have consulted a considerable number of physicians, without obtaining an accurate diagnosis of his condition. This was, perhaps, due to the fact that the stomach tube had never been used as an aid.

There is a close analogy between the stethoscope and the stomach tube. We may be able to make a diagnosis of chronic disease of the thoracic organs without a stethoscope, but it is always a help and often a necessity, and we should never neglect its use. I think the same may be said of the tube in connection with chronic diseases of the stomach. The diagnosis of the patient's condition in the earlier stage would have been very easy with the use of the tube and perhaps difficult without it.

This patient adds one more to the long list of cases in which no clear history of an attack of gastric ulcer was obtained and yet the end results of ulcer were found at operation. The immediate results of operation encourage us to advise a gastro-enterostomy, even in very severe and advanced cases of non-malignant pyloric obstruction, as an operation in which the mortality is very low and the permanent results very good.

CASE OF NEUROSIS OF ESOPHAGUS.

BY FRANKLIN W. WHITE, M.D.

The patient is a machinist, aged thirty-seven, who has had great difficulty in swallowing his food for the past month. The family history is good. His only previous illness was typhoid twelve years ago and chronic constipation, his bowels moving only once or twice a week. His present symptoms are intense pain or distress when he tries to swallow food, beginning when the food enters the esophagus and getting more intense till it passes the "end of the breast bone." This is caused by all kinds of food, both liquid and solid, but is somewhat less with liquids. He frequently regurgitates or vomits food immediately after swallowing it and thinks he has seen blood streaks in the vomitus in the past week. His appetite is good, but he is afraid to eat and has limited his diet to milk and gruels for the last two weeks, and even this liquid food can be taken only a teaspoonful at a time and swallowed with great difficulty and distress. He has had severe frontal headaches and become very anxious about himself and has been in bed for the past two weeks. There has been little loss of weight, however.

He is well developed and nourished, rather pale and nervous, reflexes lively, abdomen diffusely sensitive; general examination otherwise negative, including the pharynx. He was given a glass of water to drink, and after swallowing a mouthful he doubled up in great distress, and soon regurgitated the water back into his mouth. An ordinary soft rubber stomach tube was then passed; this caused practically no pain or distress, but at a distance of about 40 cm. from the teeth (a position corresponding to the cardia) a firm, elastic resistance was met, which gave way suddenly on using moderate pressure and the tube passed into the stomach. Ninety-five cubic centimeters of the stomach contents was withdrawn, which was perfectly normal in character.

Examination of the regurgitated fluid for blood by means of the extremely delicate benzidin test (which shows the presence of blood in a dilution of one part in 100,000) gave a negative result.

At a second visit the patient drank a few swallows of water colored with methyl blue. The tube was passed till the resistance of the spasm of the cardia was met and the blue water withdrawn by aspiration. Then the resistance was overcome by gentle pressure of the tube, which was pushed into the stomach, and uncolored normal stomach contents was obtained.

The patient was examined with the x-ray and fluoroscope, while swallowing a Riedel meal (gruel and bismuth subnitrate). No esophageal pouch or appreciable dilation was found. A diagnosis of hyperesthesia of the esophagus and mild spastic stenosis of the cardia was made and was borne out by the results of treatment.

The treatment consisted in passing the soft stomach tube several times at a few days' interval and in encouraging the patient. Bromides were given for a short time and one or two teaspoonfuls of olive oil before each meal. The diet consisted of liquids and soft solids at first.

Improvement was rapid. The distress on swallowing and the regurgitation of food almost entirely disappeared at the end of a week and the patient went back to work. At the end of two weeks he was eating everything and practically free from symptoms, save for slight epigastric distress after meals.

The diagnosis of a purely functional disturbance, hyperesthesia and mild spasm of the esophagus was not difficult in this case. It is a condition which occasionally occurs in nervous or overworked persons and may be accompanied by a gastric neurosis.

The fact that all foods were equally difficult to swallow and the intense distress on swallowing a little water in comparison with the ease of passage of a stomach tube strongly suggested a neurosis. The fact that water could be partly swallowed and that no resistance was met on passing the tube until the end was 40 cm. from the teeth showed that the spasm was in the deeper part of the esophagus at the cardia, the most common location. The elastic feeling of the stricture and its sudden giving way to pressure left little doubt of its nature. Absence of the two swallowing sounds on listening with a stethoscope over the cardiac opening of the stomach is not considered a reliable sign of stenosis.

As cardiac spasm frequently accompanies an organic lesion great care is needed, in making the diagnosis of a pure neurosis, not to overlook a possible organic cause. There was no history of a cause of true stricture, such as a chronic ulcer, or swallowing of corrosive substances, and although the severe, cramp-like pain behind the sternum, which was so striking when the patient tried to swallow even liquids, suggested ulcer or erosion, the absence of pain in passing the stomach tube and the absence of blood in the regurgitated fluids, with the slight loss of weight, seemed enough to rule out both this rare condition and incipient cancer.

The absence of a pouch or diverticulum was shown by our ability to push the tube directly into the stomach after aspirating the contents of the esophagus. The above test, with methyl blue

water and stomach tube, is one of the simplest and best to distinguish between an esophageal pouch, or diverticulum, and a simple fusiform dilatation. In the first case, the tube cannot be pushed on into the stomach, and in the second it can.

The use of the x-ray after the patient has swallowed food containing bismuth is the most satisfactory means of determining the exact size and position of an esophageal pouch. The bismuth fills the pouch and outlines it with a clear shadow.

The duration of the trouble and the actual spasm of the esophagus were too mild in this case to cause more than a very slight widening of the esophagus above the spasm.

The good results of treatment were more prompt and lasting in this case than are usually to be expected in cases of esophageal neurosis, many of which are very stubborn and prolonged.

It is almost needless to say that the treatment of the patient's general condition by rest, hygiene, psychotherapy and narcotics is, if anything, more important than local treatment by tubes, bougies or dilators, and I have no doubt that the mental effect of the passage of a tube is fully as important in showing the patient that the passage into the stomach is easy and open, as the local effect in overcoming muscular spasm.

In a stubborn case the best treatment, in addition to the care of the mental and nervous condition, is the use of large bougies — size 58 or 60 French, or of Mixter's metal dilator, in which instrument metal beads of increasing size are pushed through the obstruction on a metal guide rod.

FRACTURED SKULL WITH EXTENSIVE DEFECT OF BONE.

BY J. BABST BLAKE, M.D.

A MAN, thirty-six years old, entered the hospital for treatment of external and internal hemorrhoids. Physical examination revealed the fact (which the patient did not mention) that an accident fifteen years ago had caused a compound comminuted fracture of the right side of the cranium, and that more than half the parietal bone and a part of the orbital plate of the frontal had been removed, leaving a non-tender, pulsating area, which is not noticeable on inspection, but obvious on palpation.

The City Hospital records, Sept. 15, 1891, state that the patient was brought in unconscious and covered with blood, an eight-pound pulley having fallen forty feet and struck him on the head. A large amount of bone was removed; the dura was torn; disorganized brain substance came away, and the hemorrhage was profuse. Bleeding points were ligated, the dura stretched loosely over the brain, the scalp sutured, and a dressing applied. He made an uninterrupted recovery, leaving the hospital in three weeks.

For three years afterward he was subject to epileptiform attacks of the following character: While walking, usually in the street, he would gradually become aware of a sensation of being followed by some one. This sensation increased, until he felt a desire to look backward over his right shoulder. The sensation became imperative, but the instant he turned his head and looked over his shoulder, he fell unconscious. The nature of the attacks seems to have been similar to those described in traumatic epilepsy.

At that time he was working, and doing active exercise in the gymnasium. It was suggested that such exercise might in some way favor the development of these attacks. He omitted the exercise, though continuing his work, and the attacks quickly disappeared, and have not returned. His only symptoms at present are dizziness if he bends forward, as in tying his shoe, a considerable limitation of the field of vision of the right eye, and a slight right-sided deafness.

This patient illustrates the reverse of the course of most cases of traumatic epilepsy. Usually the attacks continue after they are once established, and, as a rule, increase both in frequency and severity, unless, as occasionally happens, they are modified by treatment, operative or general in character. It is interesting to note that the large defect in the skull corresponds closely to the condition produced by the modern operation of decompression, and it is possible that the exceptional result is due, at least in part, to this fact.

I. CASE OF ANTHRAX OR MALIGNANT PUSTULE. II. TYPHOID FEVER WITH ACUTE CHOLECYSTITIS AND PERFORATION OF GALL BLADDER. III. FOREIGN BODY IN KNEE.

BY H. A. LOTHROP, M.D.

I. This man is forty-nine years of age; a teamster. He has much to do with the handling of leather, but otherwise there is nothing in his occupation which would expose him to this type of infection. His general health has always been good. On Dec. 1, he noticed what appeared to him to be a "pimple" on the right side of his neck. This gradually increased in size and became tender and painful. As a result he came to the hospital on Dec. 3.

Examination showed we had to deal with a man whose general health was good. He was complaining of moderate constitutional symptoms, such as would be consistent with the formation of a small abscess, which was causing some toxic absorption. An unusual factor, however, was the presence of excessive vomiting and thirst. Local examination showed on the right side of the neck a circular swelling, more or less circumscribed and about two inches in diameter. The surface was raised and its center was of a dark color. This darker center was surrounded by a zone of vesicles, most of which were intact. The portion of the induration toward the maxilla was sharply defined. The lower half presented no well-marked edge, but there extended down the neck in a broad zone, over the clavicle and on to the front of chest, a swollen, red and indurated area. The amount of tenderness was moderate. His pulse was about 110 and his temperature 102°. Infection from the bacillus anthracis was suspected at the outset. Cover slips were prepared from the darkened center of this inflamed area and the bacillus anthracis was demonstrated to be present. The skin in the vicinity was prepared in the usual way, with soap and water and 70% alcohol, up to the zone of vesicles. Great care was used not to break any of these, or to touch the darkened zone within this row of vesicles. The gauze used in the cleansing was allowed to touch the skin but once.

Operation. — An immediate operation was performed. A circular incision was made around this swelling, having a diameter of 2½ to 3 inches. No instrument was allowed to touch the central mass which was being excised except on its very periphery, and there were removed all tissues down to and including the deep cervical fascia, on which were discovered a few fibers

of the sterno-cleido-mastoid muscle. The hemorrhage was only moderate. Ninety-five per cent carbolic acid was applied directly to the wounds and rubbed into the tissues and its application was followed by 70% alcohol. The wounded surface was then packed with iodoform gauze, over which a protective dressing was applied. The subsequent dressings were similar. Patient has made an uninterrupted convalescence. His temperature was normal in three days and has remained so. There has been no septic absorption. An examination of blood at time of operation was negative, so far as the presence of bacilli was concerned. Examination of the specimen showed numerous bacilli in the tissues and in the vesicle fluid, but very few were present in the tissue in the vicinity of the cut edge. The injected bacilli were fatal to guinea pigs.

II. This man of thirty-nine years, was admitted to a medical service of the hospital, suffering from typhoid fever. His case was a mild typhoid fever, without complication and he was convalescing. At the end of four and a half weeks, about 10 P. M., one evening, he had sudden pain in the right hypochondrium and also pain referred to right shoulder. There had been no previous complaints referred to this hypochondrium. An intestinal perforation was suspected. I saw him about 11 A.M. on the following morning. At that time his symptoms had largely subsided and he was comparatively confortable. His pulse was about 110 and his temperature 101°. The abdomen was not distended. There was moderate muscular spasm referred particularly to the right half of the abdomen, and the tenderness was more marked in the right lower quadrant. An intestinal perforation was suspected, but, in that his condition had improved so much in the last few hours, interference was deferred. In the course of the afternoon, however, he complained more of pain in right lower quadrant and the muscular spasm was more marked. His general appearance was less favorable. In view of his condition, an operation was decided upon.

Operation. — A median incision was made extending from the umbilicus to the pubes. On opening the abdomen, there appeared a slightly turbid fluid in considerable quantity, which was of a yellowish color, obviously stained with bile. The small intestine was examined rapidly, beginning at the lower end of the ileum. The indurated areas characteristic of typhoid ulcers were discovered in the lower end and there were patches of white exudate on the intestine, showing the presence of a moderate degree of peritonitis. No perforation of the intestine was discovered. The hand, passed through this wound to the right hypochondrium, showed the presence of adhesions about the gall bladder. It became obvious that the site of the trouble was here. The original incision was closed rapidly and a vertical incision through the right rectus muscle so as to expose the gall-bladder region was made. Without difficulty, a perforation, ¼ of an inch in diameter, was discovered on the under side of the neck of the gall bladder, through which was escaping a thick, creamy pus. This perforation was closed and the edges inverted by means of Lembert sutures. The fundus of the gall bladder was then opened and a drainage tube inserted and sewed in place. The second abdominal incision was then closed, leaving sufficient room for drainage.

The shock following this operation was not excessive and his convalescence has been uninterrupted. As you will observe, the wounds are healed, except for a small opening which marks the site of drainage, from which escapes a very moderate amount of bile. Patient is now gaining weight rapidly and suffers no particular discomfort. The fistula will probably close very shortly. Looking back over the history of this case I feel convinced that a more careful consideration of his signs and symptoms, just prior to operation, would at least have given rise to the suspicion of the presence of an acute cholecystitis with perforation.

III. This patient is a boy of seven years, who entered the hospital about ten weeks ago. Examination showed an acute synovitis of the right knee. There was no particular history at time of entrance, which would suggest a cause for the inflammation. He had a temperature of 102°, which became normal in the course of two or three days. The moderate amount of fluid which had been present was gone by the end of a week. Two x-ray pictures were taken, but he was discharged from the hospital before these were obtained. He returned to the out-patient department still complaining of discomfort in the knee and a moderate amount of fluid had reappeared. Examination of the x-ray pictures showed a foreign body in the joint and it appeared to be a broken needle. It was then learned from the mother that the boy might have fallen on a pin, such as is used in connection with phonographs. The picture showed the foreign body situated on the inner side of the knee, about equidistant from the articular surfaces of the tibia and femur, in the immediate vicinity of the internal semilunar cartilage. It was well toward the center of the joint.

Operation. — A slightly curved incision was made, more or less parallel to the direction of the fibers of the vastus internus muscle, and the inner aspect of the capsule exposed. No tourniquet was used. By means of a curved incision just anterior to the internal lateral ligament of the joint the capsule was opened above the internal semilunar cartilage. A careful search in all parts which could be exposed by this incision failed to reveal the presence of any needle. A moderate amount of clear fluid escaped from the joint. The capsular incision was then prolonged moderately and the joint approached just below the internal semilunar cartilage. The needle was then discovered situated below this cartilage and about half buried in the center of the hyaline cartilage of the tibia. The cartilage was a little eroded, so that the needle was in a small cavity and one end projected into the joint so as to be rubbed by every movement at the knee. It was about ½ inch long and undoubtedly was a fragment of a phonograph pin. The wound in the capsule and the skin incision were closed and the leg fixed by means of a splint. It is now three weeks since operation. Healing was by first intention and the convalescence was uninterrupted. He will wear fixation apparatus about one week longer and then will be allowed to move the joint carefully.

DIFFUSE PERITONITIS; DRAINAGE; INTESTINAL PARALYSIS, SECONDARY ENTEROSTOMY, WITH RELIEF OF SYMPTOMS.

BY DAVID CHEEVER, M.D.

Esther C., seven years of age, admitted to the Boston City Hospital, Dec. 8, 1906. No history of previous attacks of appendicitis. Present illness of two days' duration, pain at first in the epigastrium, later in the lower abdomen, constant vomiting, constipation.

Physical examination showed a little girl in fair general condition, with a moderately distended abdomen, extremely tender below the umbilicus and to the right. There was but little involuntary muscular spasm, no mass and but little, if any, demonstrable dullness in the flanks.

Laparotomy was immediately performed under ether anesthesia. Upon opening the peritoneum

through the right rectus muscle free pus exuded from among the coils of reddened, congested intestines. The pus was wiped out as fast as it appeared. Cautious examination with the finger showed the entire absence of limiting adhesions. The appendix was found lying over the pelvic brim, the tip necrotic and perforated. The right lower quadrant and the pelvis were bathed in thin pus, which was sponged out as completely as possible. Careful exploration led to the conviction that the process did not extend far into the left lower quadrant or above the umbilicus. The pelvis and right iliac fossa were drained with rubber tubes, wrapped in gauze and rubber tissue.

After operation the temperature fell to normal, but the general condition failed to show corresponding improvement. Vomiting persisted and approached fecal in character, distention and tympany increased, and all measures to cause the passage of gas and feces failed. Exploration of the wound and removal of the wicks showed a satisfactory local condition and no mechanical error in the operative technique to account for the obstruction. There seemed practically no doubt that death would soon occur. Forty-eight hours after the operation, primary ether anesthesia was induced in the ward, the abdomen opened in the left linea semilunaris and a distended coil of ileum drawn out, secured to the skin by one suture and freely opened. The escape of a considerable amount of fecal matter and gas was materially aided by abdominal pressure. The patient's condition did not justify any attempt at exploration through the new incision, nor more elaborate suture of the intestine to the peritoneum, and the operation was undertaken solely for the relief of symptoms by making an artificial anus, rather than for the determination of the cause of the obstruction.

The patient has finally made a complete recovery so far as the peritonitis is concerned. For many days a free discharge of pus persisted through the original incision, from the region of the lower abdomen and pelvis, and there were several attacks of transient vomiting, with the presence of acetone in the urine. The incision is now completely closed. For ten days all fecal matter passed by the artificial anus; on the eleventh day gas and fecal matter passed in small amounts by rectum. At present there is a small amount of fecal discharge from the artificial anus and formed movements by rectum. There is no probability of the spontaneous closure of the fistula, as it is a muco-cutaneous one, but the good general condition of the patient justifies the hope that the restoration of the continuity of the intestine is merely a question of operative technique.

The writer believes that this is one of a class of cases which are sometimes erroneously reported as cases of general peritonitis. Such instances have come under his observation, and it seems improbable that the very much higher percentage of recoveries reported by some observers than is the experience of others should be entirely due to perfection of technique. When the opening of the peritoneum discloses free pus bathing the coils of presenting intestines, and the examining finger finds no limiting adhesions anywhere, it is easy to mistake a diffuse, spreading, but still localized, infection for a general one. There may exist a confusion in the definition of terms: a general peritonitis may be said to be one which involves the whole greater peritoneal cavity; anything of less extent may be called a diffuse process. It seems reasonable to exclude from the definition the lesser peritoneal cavity, since its involvement in any peritoneal inflammation is uncommon and when present is a negligible factor except in certain cases of direct infection, as by perforation of a gastric ulcer, or by a gunshot wound. The writer has not been so fortunate as to have under his personal observation any case of recovery from an actually demonstrated general peritonitis, but a considerable number of cases are reported and they will, doubtless, increase with improvement in technique.

Stoppage of the intestinal current is one of the most common and serious of the complications of peritonitis. Any of the mechanical causes of obstruction may be present, but there is a large class of cases where it can be ascribed only to a simple cessation of peristalsis, due to toxic paralysis, as in the case reported above, where the subsequent course of events ruled out with reasonable certainty any other cause. It is precisely in this kind of a case as other surgeons have pointed out, that the scale may be turned by a simple enterostomy, which lessens or prevents the exhaustion of vomiting, conserves the strength and perhaps permits of nutrition until the infection may be overcome.

Reports of Societies.

AMERICAN GYNECOLOGICAL SOCIETY.

THIRTY-SECOND ANNUAL MEETING, HELD AT WASHINGTON, D. C., MAY 7, 8 AND 9, 1907, IN CONJUNCTION WITH THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

(Concluded from No. 9, p. 300.)

THE COMPARATIVE ADVANTAGES OF CATGUT AND SILVER WIRE SUTURES FOR CLOSING THE FASCIA AFTER ABDOMINAL INCISIONS.

DR. HUNTER ROBB, of Cleveland, Ohio, said the ideal suture material should be smooth, pliable, but not brittle, not too costly, easy to obtain on short notice, and above all readily rendered completely sterile. Catgut would be an almost ideal material, but when we sterilize it, short of rendering it brittle, and consequently useless, some few of the inner strands may not be absolutely aseptic; and, in fact, not a few cases of suppuration and even death have been directly traceable to the use of catgut ligatures. The cumol method probably gave the best results, but for the past few years he had had excellent results with the ordinary and chromicized catgut as prepared by Van Horn, of New York, especially when the smaller sizes were used. When, however, the larger sizes of chromicized catgut were employed, the sutures were not always absorbed, but frequently gradually worked their way to the surface of the wound and were then discharged. They were not always sterile. Bacteriological tests made in his service had shown that the knots and end of catgut sutures, even when the wound had healed by first intention, teemed with bacteria, and he felt sure that chromicized catgut was responsible for many of the skin infections encountered.

In one case of phlebitis following an amputation of the cervix in which chromicized catgut, was used, he was inclined to attribute this complication to the suture material.

He now preferred to use for the skin and peritoneum small sizes of sterilized catgut, but for the fascia he believed that silver wire offered advantages over the larger sizes of plain or chromicized catgut. These results had been deduced from recent experience and largely also from an analysis of two series of 100 cases each in which silver wire and chromicized catgut respectively were used in bringing together the deep fascia. This analysis showed that the relative incidence of infection in the deep fascia occurring after the use of catgut and silver wire respectively was as two to one. Moreover, it was noted that when suppuration occurred, it was always larger in amount and extent in the catgut cases than in the infections met with after the use of silver wire. The main objection against the use of silver wire for bringing the fascia together was, that one left in the wound a substance that might annoy the patient by sticking into the surrounding tissues. This trouble, however, could be readily averted if the suture was properly applied and the ends were turned over with a pair of thin-jawed hemostatic forceps, so that they form a ball-like end to the suture. This annoyance had to be remedied in only four out of four hundred of the silver wire sutures. Removal under cocaine was always easy and painless.

So far as the occurrence of hernia was concerned, *a priori*, this accident should be less likely to occur after the use of silver wire, as this material undoubtedly approximated the tissues for a greater length of time, and in his experience had given rise to suppuration less often. Hernia was not noted in a single case in either series, but the separation of the fascia and muscle often did not take place within the first few weeks after operation, and yet sometimes if these patients were examined some months or a year afterwards, a smaller or larger protrusion would sometimes be apparent. He had not infrequently noted such an occurrence in patients who had been operated upon by other men, and he had no doubt that others had met with the same thing in some of his cases. Consequently, so far as hernia was concerned, he did not believe that we should judge of the relative value of the suture material except in cases examined at an interval of six months or a year after operation.

Dr. Leroy Broun, of New York, said it was his custom, in closing a wound, to bring together the fascial edges with chromicized catgut. He did not rely on this entirely, but introduced, at the same time, some safety sutures of silkworm-gut at about an inch and a half apart, and he saw that these were kept in for at least two weeks, to guard against the opening of the wound by coughing, a sudden jar, or sneezing.

THE USE OF LAXATIVES IN THE AFTER-TREATMENT OF LAPAROTOMY.

Dr. Henry T. Byford, of Chicago, said that some laparotomies were of such a simple nature that the functions of the abdominal viscera were not materially disturbed thereby, and need not be disturbed afterwards by medicine. Exploratory peritoneal section, and the removal of non-adherent ovaries, were apt to be of this nature. But the majority of laparotomies represented a different problem. When there had been considerable trauma during the operation, with consequent soreness and inability to endure the pains, he applied an ice-bag to the abdomen rather than give opiates. The ice-bag and an enema containing 30 gr. of chloral would usually alleviate the pain and nervousness and sometimes the nausea, without inhibiting peristalsis. If his only object were to save life he should not bother the patients with the laxatives unless abraded or injured tissues had been left to form adhesions; but he confessed, at the risk of being considered meddlesome, that he gave laxatives in all but the simplest cases, because in those who did not really need them the bowels were more quickly relieved of the gas, and the patient then felt much better than when not so treated. Patients who had undergone a previous laparotomy generally remarked, without being asked, that they were having a much more comfortable convalescence than after the previous one in which they had either taken no laxatives, or had taken opiates for the pains.

CARE OF STOMACH AND BOWELS; POSITION AND REST IN BED.

Dr. Lapthorn Smith, of Montreal, did not allow anything whatever to go into the stomach of a patient during the first twenty-four hours. The bowels were moved by enema on the third day and every day after unless they moved naturally. If there was vomiting, calomel was used generally with bicarbonate of soda. Position depended on the severity of the cases. In hemorrhagic cases the foot of the bed was raised; or in septic cases, especially after appendicitis, the head was raised. Rest in bed for three weeks was the safest so as to improve digestion and nutrition. Twenty-one days after operation the patient was allowed to get up and to begin gentle exercise, so that by twenty-eight days she could walk about freely.

ESERINE SALICYLATE AS A PROPHYLACTIC AGAINST ATONY OF THE BOWELS.

Dr. Hiram N. Vineberg, of New York, referred to the use of this agent, saying it had a beneficial effect when given to a patient before coming out of anesthesia. It was given in doses of one-fortieth of a grain. It was the custom to give $\frac{1}{4}$ or $\frac{1}{2}$ of a grain of morphine with one-fortieth of a grain of salicylate of eserine. He thought there was less distention of the abdomen after the use of eserine in this manner.

THE INCISION AND AFTER-TREATMENT.

Dr. W. Gill Wylie, of New York, said the location of the incision varied with the internal condition. The method of closure varied according to the site of the incision. Method also varied with the condition of the bowels due to preliminary preparation.

THE AFTER-CARE OF THE PATIENT.

Dr. Herman J. Boldt, of New York, said that mobility of the patients was begun as early as was consistent with the patient's general condition. The greater number of patients might be out of bed with advantage to them within three days. A large number, even those upon whom extensive and technically difficult operations had been done, might be out of bed and placed in a comfortable chair within from twenty-four to thirty-six hours after the operation. A properly adjusted plaster bandage, adhesive, was essential for the safety of the wound. Neither the stomach nor the bowels required any special consideration unless there was some particular indication for it.

THE AFTER-CARE OF THE PATIENT.

Dr. J. Montgomery Baldy, of Philadelphia, said that rest in bed, good hygiene, diet and nursing were the principal factors in the end results. Moderate early getting up after operations was all right for patients in good general condition, but it was bad for others. There was nothing to recommend getting up in twenty-four or forty-eight hours. There was nothing to be gained, but much to be lost. That prolonged stay in bed increased the frequency of embolism and thrombosis was not true. He would admit that a surgical case might be gotten out of bed and home in

a week or ten days, but he denied that this was best for the patient, or that this meant that convalescence had been more rapid. The aim should not be to get patients home in the quickest possible time, but to give them the best amount of stored-up health and energy with which to successfully meet the future. One who had gotten out of bed with health fully restored was surely more competent to meet the necessities of every-day resistance than one who had been quickly put upon his feet with little regard to his general condition.

THE PROPHYLAXIS OF VENEREAL DISEASE FROM THE STANDPOINT OF THE GYNECOLOGIST.

The President, DR. CLEMENT CLEVELAND, of New York, selected this subject for his address. He said the position of the gynecologist regarding venereal disease was one of greater enlightenment than that of his brother of the general profession, because of his greater opportunity for observing it. His responsibility was, therefore, proportionately greater. From gynecology had come all the present day knowledge of the effects of gonorrhea in women, and the inspiration for all that was known of its lasting effects upon men. The responsibility of enlightening the public did not rest with the medical profession alone. It was not a medical or sanitary problem merely, as the causes were dependent upon social conditions beyond control of the physician. By constant study and agitation the best methods for reaching the people would be evolved. All medical schools should pay the greatest attention to instruction in venereal diseases and their consequences, and some were doing so. The student and physician could not be too often reminded of the responsibility that rested upon them, not only in the treatment of these diseases, but as regards prognosis, and sanction of marriage. Many thousands of young men with a gonorrhea uncured marry, and with the sanction of their physicians, who had not been as careful as they should have been in giving approval. For himself, he was positively convinced that the gynecologist should not play over the surface of the subject, but should get right down to the foundation of the matter and display it in all its ugliness. In this way only could there be any hope of making influence felt and expect to reach any moral advancement.

To overcome indifference and arouse an urgent public sentiment in favor of the movement, there was no more powerful argument than the fact that the greatest sufferers from these diseases were innocent women and children. Constant preaching of this one fact alone would gain more supporters for the cause than all others combined.

In closing, Dr. Cleveland thought it would be well to have a standing committee to report each year, to arrange for papers in symposium, to invite prominent men to read papers before the society, or in other ways to make prominent the vital interest that was felt. By so doing gynecologists would acquit themselves of any charge of inactivity, and at the same time have the satisfaction of feeling that they were doing their share in helping on the good work.

WORK OF HENRY GARRIGUES APPRECIATED.

DR. BROOKS H. WELLS, of New York, delivered an oration on Dr. Garrigues in appreciation of his work in introducing asepsis into obstetric practice in America.

The Association held a joint session with the American Association of Genito-urinary Surgeons, at which there was discussed "The Surgery of the Kidney."

SURGERY OF THE KIDNEY.

DR. GEORGE S. HUNTINGTON, of New York, pointed out by means of numerous lantern slides some of the congenital variations of the kidneys and ureters in reference to their development and surgical importance.

DR. LEWIS GREGORY COLE, of New York, followed with remarks on the radiographic diagnosis of renal lesions. His talk was accompanied by the projection of numerous lantern slides on the screen.

DR. CHARLES H. CHETWOOD, of New York, exhibited specimens, and presented illustrations of renal lithiasis, of pyonephrotic stone kidney, and of renal tuberculosis.

DR. FRANCIS S. WATSON, of Boston, presented the subject of calculous anuria, with especial reference to bilateral renal calculus, and to the simultaneous performance of bilateral nephrolithotomy in those cases, and to calculous anuria occurring in patients having but one kidney.

DR. HOWARD A. KELLY, of Baltimore, discussed the value and method of mensuration in vesical, ureteral, and renal work.

DR. GEORGE E. BREWER, of New York, considered the pathology, diagnosis and treatment of acute unilateral septic infarcts of the kidney; while Dr. GEORGE M. EDEBOHLS, of New York, pointed out some of the requirements of up-to-date nephrectomy.

The last session of the society was a joint one with the American Ophthalmological Society, at which the prophylactic and curative treatment of ophthalmia neonatorum was discussed.

THE PROPHYLACTIC AND CURATIVE TREATMENT OF OPHTHALMIA NEONATORUM.

DR. EDWIN B. CRAGIN, of New York, described some experiments and tests that had been made, and from these he said it was evident that in the solutions usually employed, argyrol had practically no bactericidal power over the streptococcus or staphylococcus, but with the gonococcus in strengths of 20% and 30% it was perfectly efficient. These tests also showed why the results with the 10% argyrol were not as good as with the 20% argyrol. So long as a 20% argyrol solution was efficiently bactericidal with the gonococcus in thirty seconds, so long as the gonococcus was the coccus most feared in the etiology of ophthalmia neonatorum, and so long as the clinical results were practically as good as with the use of 2% nitrate of silver, and better than with the 1% nitrate of silver, and this without the annoyance of silver irritation and staining, he felt justified in using and advocating the use of argyrol as a prophylactic against ophthalmia neonatorum.

In the curative treatment of ophthalmia neonatorum the writer had also found argyrol of great value. The absence of irritation in strong solutions, the fact that these solutions might be dropped into the eye at short intervals by the nurse without injury to the eye, and the fact that these solutions were bactericidal to the gonococcus — all these facts were in its favor, and the writer's present plan of treatment consisted of frequent irrigations of the eye with boric acid solution, every fifteen to twenty minutes during the stage of active purulent discharge, cold compresses, and the instillation of argyrol, 30% every two to four hours.

Since the completion of the bactericidal tests referred to, the writer felt that in spite of its many good qualities, argyrol left much to be desired in the treatment of ophthalmia when due to the streptococcus or staphylococcus. Some of the worst cases of ophthalmia were due to streptococcus infection, and it was hoped that in the near future a silver compound might be found which would possess the blandness of argyrol and be as germicidal to the streptococcus and the staphylococcus as was argyrol to the gonococcus. In the meantime, it seemed wise in severe cases of ophthalmia

neonatorum, which resisted the treatment by argyrol, boric irrigations and cold compresses, to make occasional use of nitrate of silver, 1% to 2% solution.

DR. LUCIEN HOWE, of Buffalo, N. Y., favored the use of nitrate of silver in 2% solution in cases of ophthalmia neonatorum. He discussed the subject from three distinct standpoints, namely, as it affects the physician, midwives, and as it affects the public. He said the percentage of blindness from ophthalmia neonatorum was greater in the rural districts, and not in the cities, where one would expect to find it.

DR. LAPTHORN SMITH, of Montreal, said that of over 1,500 obstetric cases he had had a little less than 10 instances of ophthalmia neonatorum. Whenever there was any sign of ophthalmia, he began with a 1% solution of nitrate of silver, and if in two days there was no improvement in the condition of the eyes, he increased to 2% two or three times a day. In one or two cases he had gone up to 5%.

DR. WALTER P. MANTON, of Detroit, said they had been using nitrate of silver in the Detroit Woman's Hospital for many years, 2 % solution, and they rarely ever get any catarrh reaction. They had not obtained as good results as Dr. Cragin had reported, however, from the use of argyrol in 20% to 25% solution.

The paper of Dr. Cragin was further discussed by Drs. H. Park Lewis, Walter M. Green, Henry D. Fry, Alvin A. Hubbell, Seth C. Gordon, and the discussion closed by Dr. Cragin.

CYSTIC LYMPHANGIOMA OF THE GASTRO-COLIC OMENTUM.

DR. W. FRANCIS B. WAKEFIELD, of San Francisco, reported the case of a four-year-old boy, who was brought to Dr. S. J. Hunkin, with an enormously distended abdomen. He presented no other symptoms. For at least two years the child's abdomen had been noticed to be progressively increasing in size. Laparotomy was advised. Dr. Wakefield was invited to operate, and saw the child for the first time on the operating table. Abdominal section disclosed a multiple cystoma larger than an adult head, which was broadly attached to the greater curvature of the stomach, spreading out over a small portion of the anterior and a greater portion of the posterior wall. Its attachment to the stomach was so firm that it could not be separated therefrom without danger of injury to that viscus, and it was therefore cut away as close as possible to the stomach wall. No gross pathologic change could be observed in the wall of the stomach, the cystoma having simply plastered itself over its surface. The leaf of the gastro-colic omentum, which passes from the stomach to the transverse colon, was absent, although the ordinary omental apron spread itself downward from the transverse colon over the small intestines. It seemed clear, then, after the tumor had been delivered through the abdominal incision, and the operator found himself able to look directly down upon the pancreas, that he was dealing with a cystic tumor originating in and displacing the upper reflection of the gastro-colic omentum, and that the tumor, early in its career, as it developed between the omental folds, had, by simple contiguity, spread itself over and become attached to a somewhat broad area of the stomach wall. A small cystic mass about the size of a hen's egg was found loosely attached to the head of the pancreas, and a still smaller one, about the size of an English walnut, was found attached to the serous coat of the stomach, some distance from the main tumor.

The tumor was larger than a man's head, and consisted of a number of various-sized, thin and clear-walled cyst chambers. The central portion of the neoplasm was occupied by a single cavity which made up the bulk of the cystic mass. Surrounding this central cavity on all sides were numerous smaller cystoid masses ranging in size from that of an orange to that of a pea. The walls of all the cyst chambers were thin, easily ruptured, smooth, shiny, and in general appearance resembled the omentum. The component layers of the cyst walls could not be separated. The inner walls of the cyst cavities were in many places covered by somewhat adherent, gelatinous masses, which to the feel were distinctly granular. The fluid contained within the cavities of the cystoma was clear, straw-colored, neutral in reaction to litmus, and coagulated into a solid mass on heating with a drop of acetic acid. In some of the chambers the fluid was mixed with fine crystals, oily to the touch, and microscopically identical with cholesterin. In others the presence of blood was indicated, macroscopically by imparting a dark color to the fluid, and microscopically by the presence of red cells. The cystic fluid everywhere contained leucocytes.

The author gave a detailed report of the histological examination of the walls of the cystoma.

ECTOPIC GESTATION WITH SPECIAL REFERENCE TO THE TREATMENT OF TUBAL RUPTURE.

DR. HUNTER ROBB, of Cleveland, Ohio, gave a brief review of the course of an ectopic gestation, also of the opinions of various authorities as to the treatment to be adopted in emergencies due to tubal rupture; as the patient rarely died from the hemorrhage, but more often from shock, as a rule it was better not to operate until reaction had taken place. Records of several cases treated in this way and also of experimental hemorrhages produced by cutting the ovarian and uterine arteries in bitches were given.

INCISION OF THE ANTERIOR UTERINE WALL AS THE TREATMENT OF CHRONIC INVERSION OF THE UTERUS.

DR. REUBEN PETERSON, of Ann Arbor, Mich., said that all efforts at reposition of a chronically inverted uterus must be directed towards dilating and incising the unyielding cervical ring. Pressure methods were relegated to the past. Proper treatment was operative from the start. The constricted cervical ring could be incised from above or below. The abdominal route was no easier and did not give as good results as the incision from below. The uterine wall might be incised anteriorly or posteriorly. The former was preferable. He cited a case of twelve years' standing which was successfully treated by this method, and described in detail the operative technique.

DR. I. S. STONE, of Washington, D. C., presented a study of the utero-sacral ligaments from the standpoint of their utility as uterine supports.

POST-OPERATIVE INVERSION OF THE VAGINA; A PRESUMABLY NEW OPERATION FOR ITS CURE.

DR. PHILANDER A. HARRIS, of Paterson, N. J., said that access to the field of operation was made through a suprapubic median line abdominal incision. The round ligaments were sought and dissected from their imbedments. The vagina was well pushed upward with a staff. A small hole was cut in the vagina upon its right side, and another opposite upon its left. The mucous membrane of the fundus of the vagina between and about these penetrations was curretted. The right ligament was drawn through the apertures near the top of the vagina from right to left. The left ligament was then drawn through the apertures of the vagina from left to right. The distal end of each ligament was then drawn taut, and sewed as high as possible with catgut to the larger portion of its fellow. After sewing the distal portion of each ligament to the proximal

portion of the other ligament, the through-and-through sewing was continued at the fundus of the vagina in such a manner as to repeatedly penetrate the ligaments which it covered.

OFFICERS.

The following officers were elected: President, Dr. J. Montgomery Baldy, of Philadelphia, Pa.; Vice-Presidents, Dr. I. S. Stone, of Washington, D. C., and Dr. Malcolm McLean, of New York; Treasurer, Dr. Chas. P. Noble, of Philadelphia, Pa.; Secretary, Dr. J. Riddle Goffe, of New York. Member of the Council, Dr. Clement Cleveland, of New York.

Philadelphia was selected as the place for holding the next annual meeting, in 1908.

Book Review.

Clinical Diagnosis. A textbook of clinical microscopy and clinical chemistry for medical students, laboratory workers and practitioners of medicine. By CHARLES PHILLIPS EMERSON, A.B., M.D., Resident Physician, the Johns Hopkins Hospital; Associate in Medicine, Johns Hopkins University. Philadelphia and London: J. B. Lippincott Co. 1906.

This volume furnishes abundant evidence, if evidence were needed, of the great amount of work that has been accomplished in the clinical laboratories of the Johns Hopkins Hospital. Here will be found collected and collated a great number of carefully observed facts. In addition to the author's personal experience he utilized in the preparation of this book the clinical records of the hospital since its opening in 1889. For a number of years Dr. Emerson was the director of the Clinical Laboratory and had charge of the systematic course in clinical microscopy which, since the foundation of the Johns Hopkins Medical School, has held an important place among the studies of the third year students. It was the first well-equipped clinical laboratory established for teaching purposes and providing ample accommodation for a large class of students. It was built near the wards and was independent of the laboratories of chemistry or pathology. Without doubt the conception of this laboratory originated with Dr. Osler. The first instructor to be placed in charge was Dr. Thomas B. Futcher, who as early as 1896–97 gave an excellent systematic course in laboratory methods of clinical application. To Dr. Futcher is due the credit of developing this new department in clinical teaching. His efficient work was extended and amplified by Dr. Emerson.

As the author states in the preface the subject is presented from the clinical rather than the laboratory point of view.

That data of great value have been collected can be readily understood when it is known that eighty microscopes in the hands of trained students were used in the examination of eighty specimens of a single patient's blood or sputum. The most interesting findings were drawn by an artist who was always within call.

There is an admirable introduction by Dr. Osler. We wish his wise words might sink into the minds of all clinical teachers. "In medical education the all-important problem is to give a man the knowledge he can use. In our modern system much of the training is rendered ineffective, as it has not been sufficiently prolonged to become part of a man's intellectual or bodily mechanism. A brief course of six weeks on any practical subject is almost useless and in some may be positively dangerous." In his closing paragraph he says, "But the aim of a training such as this book implies is to send out into practice men able to give patients the benefit of modern scientific methods in the diagnosis and treatment of disease — men who use the microscope, who examine sputum and who use the stethoscope, and who can do the routine urine and blood work with confidence."

The book contains a great deal of original material such as is usually published in monographs or journals. As examples may be cited a study of the excretion of sodium chloride in the urine of pneumonia patients, the sputum in chronic bronchitis, the accurate determination of hemoglobin in a large number of healthy persons, and many blood counts.

The first section deals with the sputum, and it is the best we have seen in any treatise on clinical diagnosis. As the author says, the proper examination of the sputum is fast becoming a lost art. To many a student of the present day it simply means a search for tubercle bacilli. He does not know "that our fathers who never saw a germ could still diagnose and follow cases with an acuity with which he usually does not credit them."

Over 200 pages are devoted to the urine. The chemical study as well as the microscopical is well presented. We are pleased to note that Arnold's modification of Volhard's (misspelled Volhardt) method for the quantitative determination of the chlorides is given. The procedure, although used by the leading clinical chemists, has not found its way into the standard textbooks. The section on the feces is less complete than that on the urine.

The portion of the book dealing with the blood is especially rich in original matter. The importance of accuracy in clinical hematology is emphasized. The Gowers, Dare, Sahli and other hemoglobinometers used in the hospital are standardized against a new Miescher, which is more accurate. The author hopes that the present reactions against the Tallqvist scale will lead practitioners to adopt some instrument requiring less guess work.

The text is illustrated by a large number of splendid original drawings that will be of great aid to students as the actual appearances of the specimen have been accurately reproduced.

We regret to say that the book is poorly written. The author is careless in his diction. He writes in too colloquial a style, and clearness of statement is often lacking. Some of the clinical methods are incorrectly described, and not a few other errors have been noted.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 5, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

PLAGUE IN INDIA.

THE plague situation in India, to which each year the attention of the civilized world is directed, is of far reaching interest and importance. Since the beginning of England's rule over this eastern country one of the very greatest sanitary problems which it has had to face has been this destructive disease. That there is yet much work to be done before a final solution is reached is shown by the frightful yearly mortality.

Renewed interest has of late been excited in the matter through a letter which the King of England has addressed to the Viceroy of India showing his deep sympathy with the sufferings of the people and the need of the adoption of measures successfully to combat the disease. Our contemporaries, the *British Medical Journal* and the *Lancet*, both comment on this letter and discuss at considerable length editorially the present situation. Precisely what the measures of relief may be are apparently not yet definitely determined, but so far as outlined will probably consist in the organization of four or five administrative centers in places where plague is endemic. In these centers will be stationed a well equipped medical department, familiar with the conditions, and under its direction all methods at present known of combating the disease through fumigation, disinfection, destruction of rats and other vermin and a painstaking pathological and bacteriological study will be systematically carried out.

From the standpoint of epidemiology a study of the history of plague in India is a matter of the very greatest interest. The disease appears to have been prevalent in India for many years, but its official recognition under the present government took place on Sept. 23, 1896, when it visited Bombay. During the eleven years which have supervened between that time and this it is estimated that upwards of five and a half million people have died of it. It is not known how the fatal infection reached Bombay. It may have been conveyed from Hongkong or from disease centers in Persia or Arabia. That it has spread widely from Bombay is a fact of very recent history. Last June Mr. Morley informed the House of Commons that upwards of a million deaths occurred in each of the years 1904 and 1905. Last year the situation improved somewhat, the mortality sinking to only half a million, but this year again the situation was worse than ever before, inasmuch as 642,000 deaths occurred in the first four months, a record which has never been exceeded for the same period. This is certainly a remarkable showing in view of the fact, as Mr. Morley asserted, that the government of India has given most unflagging and energetic attention to measures for exterminating or mitigating the epidemic. It is, however, an interesting commentary that much of this effort was unavailing because an attempt to discover the true pathology and etiology of the disease was in great measure neglected. This mistake cannot again be repeated, and experimental methods of dealing with the scourge are fortunately becoming less and less necessary as knowledge of its etiology and modes of transmission advance. Haffkine's discovery of a method of plague inoculation, brought out in 1897, was appreciated by the Indian Government, but through an unfortunate misunderstanding his continued service has been hampered, it is to be hoped, however, only temporarily. In 1905, through the suggestion of the Lister Institute, systematic work was organized by Dr. C. J. Martin, its director. Since then a scientific commission has been at work in India directing its attention especially to the spread of plague among rats and of means of contagion. Through these researches it has been established that the bacillus of plague is carried from rat to rat by fleas, and that the rat flea may also be a parasite of man, and, in the second place, even when grossly contaminated that floors and walls do not long retain the infection. In 1905, also, the Royal College of Physicians of London presented a memorandum to the Secretary of State for India calling attention to the world-wide danger of such an epidemic as has existed in India since 1896. It was urged that a more liberal staff of investigators should be employed and that a special sanitary service should be established. Mr. Morley has also placed him-

self among those who believe that not so much has been done by the local government as might have been possible, and doubts "whether the last word of medical science and of administrative skill has really been said." The attitude of the medical profession has of late been one of considerable skepticism in this regard, and it has from time to time so expressed itself.

It is certainly to be hoped, with the appalling death-rate which this year has already brought forth, and with the increasing knowledge which the laboratory is providing, that more stringent measures than ever before will be taken to eradicate or markedly diminish the prevalence of a disease, the continued existence of which is rapidly becoming a reproach to modern medical science. We have no doubt, with the expresse dinterest of His Majesty and the formation of a more adequate medical staff, that before many years have elapsed plague in India will be as little known as cholera or yellow fever in this country. No efforts should be spared to hasten the day.

REPORT OF THE CARNEY HOSPITAL FOR 1906.

THE Carney Hospital in South Boston ministers primarily to a large and populous section of the city, and has for many years been accomplishing a beneficent work in caring for the sick and at the same time developing its resources and methods in accordance with progressive ideas. This hospital is now the third largest in Boston, and, although under the direct charge of Roman Catholic Sisters of Charity, it is entirely non-sectarian in its reception and care of the sick. At present the hospital has about two hundred beds and receives patients from various parts of New England and the British provinces, the greater number of whom pay nothing for their care. About twenty-six hundred patients are treated in the wards yearly, and many times this number in the out-patient departments. This hospital has for years filled a particularly valuable function in that it receives persons suffering from chronic disease who are given no welcome elsewhere, except at the almshouse hospital on Long Island. The progressive policy which has marked the hospital for many years has brought it to a state of efficiency in which those primarily interested in its development must take a profound satisfaction. It is no doubt generally known that some years ago the system of graded services of visiting physicians and surgeons was adopted on the surgical side with Dr. John C. Munro as surgeon-in-chief. We have recently had occasion to call attention to the fact that this policy has also been adopted in the medical service of which Dr. Henry A. Christian has been appointed physician-in-chief. This method of conducting a hospital service has proved its usefulness elsewhere, and it is much to the credit of the Carney Hospital that it has overcome the conservatism of long usage in this community and adopted a method which on the whole must conduce to a closer study of the patients and to the furtherance of medical science.

It may not be generally known that it was at this hospital that the late Dr. John Homans first demonstrated to the medical profession in New England the possibility of operating upon ovarian tumors. Inasmuch as Dr. Homans was one of the first surgeons in the world to advocate this procedure which at that time seemed an extreme of radicalism, the Carney Hospital may well take to itself a certain credit for having offered its facilities to this pioneer work. Founded by Andrew Carney in 1863, the hospital began its career by treating fifty-three patients in that year. In 1906 twenty-five hundred patients were treated in the wards and fifty-six thousand in the out-patient department. With so creditable a past the future of the hospital seems equally assured. It is also not to be questioned that it will represent, even more than it has hitherto done, the progressive tendency in hospital management under the régime which has now been perfected by the appointment of a physician-in-chief having general oversight of all medical cases.

FINAL STATISTICS OF JULY FOURTH.

FOR five years past the *Journal of the American Medical Association* has made a valuable statistical inquiry into the injuries resulting from the celebration of July Fourth with special reference to tetanus. As a result of this inquiry, it appears that the total casualties occurring July Fourth this year were 164 killed and 4,249 injured, many of these latter permanently maimed. This showing, however, is not altogether discouraging when compared with 1906, particularly as regards tetanus. This year there were 73 tetanus cases as contrasted with 89 last year. In 1905 there were 31 more cases than this year; in 1904, 32, and in 1903, 342. It is evident, therefore, that the wide protest against tetanus-producing toys has resulted in a definite awakening of the public conscience. Tetanus, however, still continues to cause more deaths than any other single agency,

but gunshot wounds, giant crackers, and explosions come high in the list. Perhaps the most deplorable fact in the entire situation is that 31 persons were burned to death through carelessness, most of them being young girls and children. The figures which the *Journal of the American Medical Association* collects each year, and we trust will continue to collect, are the strongest possible argument for a modification of present methods of celebration. The figures should be widely advertised.

MEDICAL NOTES.

Yellow Fever in Havana. — It is reported that a case of yellow fever has appeared in Havana, being the first this summer.

Smallpox in Vienna. — The statement is made that within the ten days ending Aug. 28, 80 cases of smallpox have been reported in Vienna. Free vaccination stations have been established which are eagerly being sought by the people.

Plague in San Francisco. — It is reported that during the summer 9 cases of bubonic plague have been discovered in San Francisco and 7 deaths have occurred. No alarm is felt as to the spread of the disease, but incoming vessels are being carefully inspected.

A New Surgical Journal. — A new surgical journal with the title *Archives générales de Chirurgie*, has begun publication in Paris under the editorial supervision of Professors Lannelongue and le Dentu and Doctors Nové-Josserand, Picqué and Mauclaire. It is designed that this publication shall appear monthly, and that each number shall contain three original articles, abstracts of original papers on general surgery, gynecology, the surgery of infants, orthopedic and urinary surgery. There will in addition be book notices and a bibliographical index of surgical literature. This first number indicates a very carefully edited and comprehensive discussion of surgical matters and the journal no doubt will take a place of importance among periodicals devoted to surgery.

A Stimulus to Vaccination. — In view of the fact that smallpox prevails to an alarming extent in certain parts of the State of Illinois, the State Board of Health has had printed large posters which it requests shall be posted in conspicuous places. In addition to certain facts regarding smallpox, its nature, and its supposed means of contagion, five photographs are reproduced, four of them representing smallpox patients in various degrees of eruption, and another illustrative of smallpox contagion in the absence of vaccination. The pictures are unpleasant and should at least do something toward warning the people against exposing themselves unnecessarily to the disease through neglect of vaccination.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Sept. 4, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 33, scarlatina 23, typhoid fever 19, measles 12, tuberculosis 38, smallpox 0.

The death-rate of the reported deaths for the week ending Sept. 4, 1907, was 21.14.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Aug. 31, 1907, was 231, against 227 the corresponding week of last year, showing an increase of 4 deaths and making the death-rate for the week 19.77. Of this number 119 were males and 112 were females; 224 were white and 7 colored; 163 were born in the United States, 60 in foreign countries and 8 unknown; 53 were of American parentage, 149 of foreign parentage and 29 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 28 cases and 0 deaths; scarlatina, 20 cases and 0 deaths; typhoid fever, 18 cases and 1 death; measles, 20 cases and 2 deaths; tuberculosis, 40 cases and 15 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 8, whooping cough 1, heart disease 26, bronchitis 5 and marasmus 10. There were 14 deaths from violent causes. The number of children who died under one year was 88; the number under five years, 106. The number of persons who died over sixty years of age was 37. The deaths in public institutions were 84.

There were 0 cases and 0 deaths reported from cerebrospinal meningitis during the week.

Dr. Robert W. Lovett, a Member of the Massachusetts State Board of Health. — Governor Guild has presented the name of Dr. Robert W. Lovett, of Boston, as a member of the Massachusetts State Board of Health, to fill a vacancy caused by the resignation of Dr. John W. Bartol. Dr. Lovett's work in orthopedic surgery, and particularly that which relates to the proper seating of school children and allied matters, should make him a particularly valuable member of the board.

NEW YORK.

CHILDREN'S HOSPITAL AT ROCKAWAY BEACH. — The New York Association for Improving the Condition of the Poor has completed plans for a children's hospital to be erected at Rockaway Beach, on a site, 1,000 feet in length, which the city has agreed to reserve for it on the new five-mile beach which it has acquired for a seaside park. The hospital is to consist of fourteen pavilions, three stories in height and surrounded by broad verandas. The two pavilions at either end of the series will be placed parallel with the ocean shore and the others at right angles to it, and each pavilion is to accommodate 60 patients.

INSPECTION OF WATER SHEDS. — At a meeting of the New Jersey State Water Supply Commission held on Aug. 27 it was decided to make a complete scientific inspection of the Rockaway, Pequannock and Passaic watersheds, and also of the sites of the proposed dams at Mountain View and Singac. It is by the construction of these two dams that it is proposed to form a large lake, the estimated cost of the entire undertaking being $7,000,000. This lake will flood several villages of Northern New Jersey and render necessary a change in the main line of the Delaware, Lackawanna & Western Railroad, as well as minor changes in the lines of three other railroads. The water thus stored up will be the property of the state, and is to be sold for drinking and manufacturing purposes. It is the design of the Water Commission to so conserve the present potable supply that great corporations may not impound water and sell it at exorbitant rates to municipalities.

SEATING OF SCHOOL CHILDREN. — It is stated that for the first time in a number of years the public school authorities will enter on the new school year with a fair prospect of providing, within a reasonable time, sittings for all the pupils entitled to attend school. When Mayor McClellan was elected he declared that this would be one of the great aims of his administration, and during the past year the progress in providing accommodations by the enlargement of old school buildings and the erection of new ones has been substantial, while the plans for the ensuing year will secure even better results. The total number of new sittings available when the schools open on Sept. 9 will be 50,185; 46,085 in the elementary schools and 4,100 in the high schools. Owing to the more rapid growth in population in Brooklyn, and also partly to the fact that it has not in the past received quite so much attention as it really was entitled to, that borough will get a slightly larger number of new sittings than Manhattan. These will amount to 17,700, as against 17,350 for Manhattan.

FIRE IN THRALL HOSPITAL. — A serious fire occurred on Aug. 24, in the lower portion of Thrall Hospital, at Middletown, N. Y., by which the lives of 26 patients were endangered. One of these, the wife of Horace Hall, of Ridgebury, had been operated on just before the fire broke out, and was still under the influence of ether when she was carried from the building by her husband. Arthur Thornley, an orderly, performed heroic service in the work of rescue, and was so severely burned that it was thought at first that his injuries would prove fatal. After the fire was over all the patients were moved back to the hospital, as the upper floors were not reached by the flames.

INTERNATIONAL ZOÖLOGICAL CONGRESS. — The members of the Seventh International Zoölogical Congress, recently in session in Boston, arrived in New York on Aug. 26 for a week's stay. On the 27th a dinner was given for them at the Majestic Hotel, and later they attended a reception and entertainment at the American Museum of Natural History as the guests of the trustees and officers of the museum and of the New York Academy of Sciences. During the evening they listened to a number of brief lectures at this institution, one of them being by Prof. Henry Fairfield Osborn, who has just returned from an expedition to Egypt in which the explorations in the Fayoum brought to light some remarkable bones of the eocene period. On Aug. 29 they were the guests of the New York Zoölogical Society at a novel luncheon served in the Lion House at the Zoölogical gardens in Bronx Park, with a gallery of lions, tigers and leopards as spectators. A long table, set for 250 persons, ran the full length of the building. On one side was an embankment of palms and on the other the row of cages, where the animals were pacing back and forth and from time to time gave out roars which completely drowned the music of the band hired for the occasion. In the evening the zoölogists attended a reception given in their honor at the New York Aquarium, at the Battery. The entertainments of the week also included an excursion to West Point and Garrisons, opposite, tendered by Professor Osborne, who has a beautiful country-seat at the latter place, situated on one of the loftiest points of the Hudson Highlands.

Mortality Statistics. — The condensed quarterly report of the Bureau of Records of the New York City Health Department for the three months ending June 30, 1907, shows that the mortality in the city during the quarter represented an annual death-rate of 17.93, as against 18.29 in the corresponding quarter of 1906. The corrected death-rate, excluding non-residents and infants under one week old, was 17.06 in 1906, and 16.74 in 1907. The number of deaths during the quarter was 19,146, as against an average of 18,436 for the corresponding quarters of the preceding five years, producing, with the estimated population, a death-rate of 18.95 per 1,000; a decrease of 1.02 points. Comparing the number of deaths from the principal causes with those of the preceding quinquennial averages of the corresponding quarters, corrected to correspond with the increase of population, the following decreases are found: malarial fevers, 12; smallpox, 29; measles, 82; diphtheria and croup, 126; tubercular diseases other than pulmonary tuberculosis, 51; cerebrospinal meningitis, 267; apoplexy and softening of the brain, 75; acute bronchitis, 183; lobar pneumonia, 307; diarrheal diseases under five years of age, 185; Bright's disease and acute nephritis, 184; accidental causes, 92; suicides, 69. Those showing increases were the following: typhoid fever, 37; scarlet fever, 16; whooping-cough, 9; influenza, 24; pulmonary tuberculosis, 33; cancer, 56; organic heart disease, 430; broncho-pneumonia, 218; sunstroke, 8; homicide, 17. It will then be seen that the only marked increases have been in broncho-pneumonia and organic diseases of the heart, while the decrease in deaths from lobar pneumonia, cerebrospinal meningitis, Bright's disease, and diphtheria is very gratifying. Another source of gratification is the decrease in mortality among infants and young children. The deaths under one year of age decreased 225, under five years, 797, and between five and sixty-five years, 379; while those at sixty-five years of age and over increased 92.

Obituary.

SENECA D. POWELL, M.D.

Dr. Seneca D. Powell, for many years a prominent surgeon in New York, died on Aug. 24 at Greenwich, Conn., to which place he had retired about three years ago on account of failing health. He was a native of Alabama, and was born on Jan. 5, 1848. At the outbreak of the Civil War he was a cadet in the University of Alabama, and, leaving that institution, he served as a volunteer in the Confederate Army until the close of the war. He then studied medicine, and was graduated in 1869 from the medical department of the University of Virginia and in 1870 from the New York University Medical School. In 1871, after serving as interne at Bellevue Hospital, he was appointed an assistant inspector in the New York Health Department, and shortly afterward clinical assistant to the chair of theory and practice of medicine in Bellevue Hospital Medical College. From 1879 to 1882 he was adjunct professor of surgery in the New York University Medical College. In the latter year he became connected with the New York Post-Graduate Medical School and Hospital as lecturer on surgical dressings, and since 1887 he had been professor of clinical surgery in that institution. He was visiting surgeon to St. Mark's Hospital, as well as to the Post-Graduate Hospital. He was vice-president of the Medical Society of the County of New York in 1891 and president in 1893. In 1895 he was vice-president of the Pan-American Medical Congress at Washington, and in 1898 president of the New York State Medical Society. Dr. Powell was well known as a writer, especially on brain surgery and the surgical uses of phenol. He devoted much time and attention to the toxicology of this drug, and his services in demonstrating the efficacy of alcohol as an antidote to it are deserving of lasting remembrance.

Current Literature.

Medical Record.

2. Gaertner has studied extensively the black deposits found post-mortem in the lungs, bronchial glands, spleen, liver and kidneys, and their differentiation from pigment. The effects of dust in man depend on the kind of dust, amount, constancy of presence, susceptibility of the individual, rapidity of absorption, chemical reaction of the tissues, and amount of irritation present. Dust is at once driven into the alveoli, the smaller particles are absorbed, while the larger cut their way into the lung tissues. Hemorrhages, chronic bronchitis and pneumonia are produced. The author has proved by tests that this material consists of coal-dust, soot, etc. Absorption is favored by inspiration and the particles pass into the lymphatics, which communicate with the subpleural peribronchial and perivascular lymphatics. From these it is carried to the bronchial and tracheal glands. Lymphadenitis and periadenitis develop, and cicatricial tissue forms with contraction; or an acute process goes on with suppuration, and may

extend to the pleura, bronchi, veins, arteries, heart and pericardium. The gland may become calcified and be conveyed by perforation into the air passages and coughed up. The foreign substances may enter the blood stream and be carried to the other organs. In the spleen the pigment is found along the smaller arteries and in the marginal zones of the Malpighian bodies. In the liver it is in the periportal interacinous tissues. In kidneys it is rare. It may be differentiated from micrococci by lying mostly in the cells which germs do not do, and by staining differently. Hydrochloric acid distinguishes it from putrid products of the epithelium.

THE NEW YORK MEDICAL JOURNAL.
AUG. 10, 1907.

1. *EDGAR, J. C. *The Urine of Pregnancy.*

7. RUGH, J. T. *An Unpleasant Experience with Ethyl Chloride.*
8. BERNART, W. F. *Mercuric Values in the Treatment of Syphilis.*

1. Edgar's article reports further investigations of the urine of pregnancy, largely confirming the results published in a previous article. He lays great stress upon the importance as a danger signal of increased ammonia and undetermined nitrogen percentages in the total nitrogen of the urine. Scanty amount of urine, albumin and casts are significant when they are present, but even though these are absent the patient may be on the verge of eclampsia. Cases are reported in which the excess of ammonia and of undetermined nitrogen was the earliest evidence of trouble which later developed.

2. Dana, by means of an ingenious form of graphic representation, describes the typical symptoms of the four chief types of aphasia: (1) the frontal or fronto-capsular characterized by aphemia, with retained ability to read, write and understand; (2) parieto-occipital aphasia, characterized by alexia, with ability to speak, write and understand, associated with hemianopsia; (3) temporal or temporo-parietal aphasia, characterized by anomia, some mind deafness, paraphasia, much agraphia and alexia, without hemiplegia but with some astereognosis, anesthesia and ataxia; and (4) fronto-lenticular aphasia, the common mixed aphasia, characterized by aphemia with much agraphia, alexia, mind deafness and deafness with hemiplegia. The chart by which each case is represented includes twenty-two functions tested and recorded as "normal," "slightly impaired," "seriously impaired" or "absent." In conclusion, a short discussion of each of the more important of these functions is given with the anatomical locations and significance of impairment.

5. Lucas reports experiments dealing with the physiology, normal and pathological, of the ureters. It has previously been demonstrated that the ureters have peristaltic activity. Lucas observed that the peristaltic waves are markedly influenced by ether, still more by chloroform and to some extent by other drugs. Chloroform caused marked retardation of the peristalsis; caffein produced marked stimulation. Ligation of the ureter caused blocking of the peristalsis below the point of ligation and marked increase above it. The intra-ureteral pressure in the pelvic portion of the ureter is fairly constant; that in the lower portions is variable and may be in excess of that of the renal pelvis without a back flow of urine.

4. Adler discusses the desirability of a practical clinical method for determining the alkalinity of blood. He notes the two general methods by which the reaction of a fluid may be quantitatively measured: (1) titration to an end point, and (2) determination of the H and OH ionization. The former yields information concerning the amount of base or of acid present in a solution, but no direct evidence concerning the exactness of the equilibrium. The latter yields no direct information regarding the absolute amounts of base or of acid in the solution but gives evidence concerning the intensity of the alkalinity, the condition of the equilibrium. Heretofore only titration methods have been used on account of the difficulty of the technic and the want of an indicator to show the slight degree of the ionization met in the blood serum. Salm, however, has shown that rosolic acid and neutral red give sufficiently sharp indications at the degree of ionic concentration of the blood. Adler finds that rosolic acid with 1 cc. of rabbit's blood gives a pink color which can be compared with a standard. By excluding the corpuscles and working only with serum, confusion from the laking of blood and liberation of the color of the corpuscles can be avoided. A drop of serum from a capillary tube produces a strongly marked red color when allowed to fall on prepared rosolic acid test paper, which contrasts well with the delicate salmon pink of the unchanged parts of the paper. The red color indicates alkalinity. The serum in two cases of diabetic coma and in one case of meningitis with acetonuria did not produce this change in color, but the blood was alkaline in cases of meningitis without acetone in the urine.

7. Bunting by means of hemolytic poisons (ricin and saponin), intravenously injected into animals, has been able to produce experimental anemias closely simulating, both in blood picture and in changes of bone marrow, the primary anemia of human beings. Simple bleeding or slower administration of these poisons on the other hand merely produced an anemia of the so-called secondary type. Bunting considers that the results of this and of other work justify the conclusion that pernicious anemia is due to the absorption of hemolytic substances in such quantity that not only the blood but also the bone marrow is attacked, the typical blood picture being due to disturbance of the blood-forming function of the bone marrow. Secondary anemias, on the other hand, may be attributed to causes which act on the blood only, the bone marrow being unaffected. As to the origin of the hemolytic agent or agents assumed in this theory of pernicious anemia we have almost no knowledge, but there is much reason to suspect absorption from the alimentary tract or the oral cavity.

9. Royster discusses the subject of dislocation of the shoulder complicated by fracture of the neck of the humerus, with a report of 4 original cases and a review of the literature. The condition is probably more frequent than is recognized and its description in textbooks is generally inadequate. The diagnosis is difficult; in some cases even the x-ray may leave one in doubt. Experience long ago showed that leaving the dislocation unreduced until the fracture had united was almost certain to render reduction impossible. Immediate reduction of the dislocation is in most cases impossible. The most favorable results have followed operative treatment. The incision to be preferred extends from the acromial process directly downward through the fibers of the deltoid or between the

deltoid and the pectoralis major. In recent cases reduction is usually easy. In old cases there is often great difficulty; different operators have employed the gimlet, corkscrew or hook. The bone fragments are then adjusted and rarely require wiring. The arm should be put up in abduction, best retained by a pad in the axilla, a shoulder cap of plaster of Paris and a roller bandage. Fixation should not be kept up more than two weeks.

3. Butlin undertakes the study of auto-inoculation of cancer as preparatory to the study of the communicability of cancer from one human being to another. He points out the difficulties of animal inoculation. Even implantation is not easy, inasmuch as any sepsis will prevent inoculation. Most cancers having an exposed surface for contact are septic. These difficulties explain the rarity of the cases of auto-inoculation. He insists on three conditions: (1) both growths must be the same and communicable; (2) their identity must be proved microscopically; (3) the primary disease must be demonstrated. He reports 16 cases, of which 13 fulfill the requirements. Three cases were from one labia vulvæ to the other; 3 in the larynx; 1 from one lip to the other; 1 in the jaws; 2 from the kidney to lower down in the urinary tract; 2 cases of transference by rubbing with the hand; and 1 case from the uterus to the vagina. This last case is of special interest as the contact cancer was cylindrical carcinoma in the vagina, which is lined with squamous epithelium. He considers the possibility of implantation of cancer by "infected" instruments as a real danger in surgery.

3. Gordon emphasizes the necessity of the examination of the heart of all patients in both the erect and recumbent positions. Some of the variations noted are, that the recumbent position raises and narrows the cardiac dullness, the difference in width being about three quarters of an inch in normal cases, much more marked in enlargement; and that the recumbent position increases the second sounds, especially the accentuated pulmonic second.

Certain murmurs are heard in the erect but not in the recumbent position, and *vice versa*.

Gordon used the ordinary methods of auscultation and percussion. Another observer, Franze, in the current number of the *British Medical Journal*, has taken up the question of postural differences as found by the orthodiagraph. The orthodiagraph also finds the heart at a lower level on standing, but finds that the actual width of the heart is narrower on standing than on lying.

4. Robertson and Young, by the advantage of an improved histological technique, bring forward the new evidence of five cases in support of the contention that carcinomatous tumors are etiologically related to a special protozoan organism. In these 5 cases they find certain cyanide-fast bodies, which appear as spherical intranuclear threads, spirals and ameboid forms. Polynuclear leucocytes manifest a strong chemotaxis towards these bodies. [R. I. L.]

2. Hildebrandt has made synthetically a number of oxybenzyl derivatives of tannin, the graphical formulæ and properties of which are given in this article. The thymol derivative is recommended as a substitute for tannin itself over which it possesses the advantages that it is insoluble in acids, therefore does not irritate the stomach, and that it is tasteless. This drug, the trade name of which is tanno-thymal, possesses marked astringent power, and is not toxic or irritating.

3. Baumgarten recommends tannothymal, the new drug described in the foregoing article, as an astringent to control diarrhea. In 3 cases which resisted other forms of treatment good results were obtained.

4. Experimental work done with H. Meyer leads Bach to the assumption of an inhibition center in the medulla for the light reflex of the pupils. They have observed rigidity of the pupils and myosis after section of the medulla near the calamus scriptorius, and rigidity with pupils of medium width after laying bare the floor of the fourth ventricle. In the latter case the light reflex was immediately restored on cutting across the medulla in the *upper* portion of the floor of the fourth ventricle, probably owing to cutting of the nerve fibers leading away from the inhibition center.

6. Neurath analyzes the literature of congenital defective function of the muscles supplied by the cranial nerves. Most frequently the eye muscles are involved, either alone, or with the face; sometimes there are deformities of the external ear, or other malformations. Usually the nuclei of the nerves supplying the affected muscles are found either aplastic or degenerated. In Neurath's case, however, the nuclei were found intact, and it seems probable that there was a congenital aplasia of the muscle itself.

15. Stadelmann and Wolff-Eisner report a case of "typhoid septicemia" in which none of the usual symptoms of typhoid were present except enlarged spleen and fever; the diagnosis was made only on the bacteriological findings. At the autopsy on the twenty-third day of the illness, only trivial lesions were present in the intestines, so that the post-mortem diagnosis of typhoid could be made only from the cultivation of typhoid bacilli from the bile. Such cases as this lead them to consider typhoid as a septicemia, the symptoms being due to the action of endotoxins. The latter produce in small doses a rise of temperature, in large doses a fall. This explains why in the guinea pig the experimental typhoid infection runs with subnormal temperature and rapidly leads to death or recovery; for the serum of this animal possesses greater bacteriolytic power than that of man, and the dose of endotoxin set free at any one time is therefore larger. A discussion of the pathogenicity of the colon bacillus, with the report of a case of sepsis due to it, ends the paper. [W. T.]

DEUTSCHE MEDIZINISCHE WOCHENSCHRIFT. No. 26. JUNE 27, 1907.

1. *STRASBURGER, J. *Influence of the Elasticity of the Aorta upon the Relation of Pulse Tension to Systolic Heart Pressure.*
2. *EWALD, C. A. *Idiopathic, Spindle-Shaped Dilatation of the Esophagus.*
3. *GRÜNBAUM, D. *Milk Secretion after Castration.*

5. *HAUSCHILD. *"Euferrol."*
6. GROEDEL, T. *Discharge of Appendix through Rectum with a Septic Peritonitis.*
7. ZUELZER, R. *An Orthopedic Chair Brace.*

1. Strasburger's researches on the elasticity of the aorta in arteriosclerosis have shown that in this condition the distensibility is diminished. This he regards as a compensatory measure. These results are directly opposite to those obtained by Thoma, who, the author claims, worked by faulty methods. Since systolic heart pressure is dependent upon a constant expulsion time and also upon the elasticity of the artery walls, chiefly that of the aorta, it is evident that investigations of the volume changes of the aorta, with different pressures and at different ages, is very important. Strasburger thinks that the results of his estimations of the capacity of the aorta, when compared with blood pressure readings, prove many hitherto conjectural points about the circulation. The article is accompanied by charts.

2. Ewald reports a case of spindle-shaped dilatation of the esophagus, which he followed for three years and in which the diagnosis was made before death. The autopsy showed no adequate cause. There was no degeneration of the vagus nor was the microscopic condition of the esophageal muscle such as would occur if the vagus were degenerated. The specimen showed that the dilatation occurred in the lower two-thirds and the circular muscles were hypertrophied to 3 mm. in thickness. A spasm of the cardia and hypertrophy and subsequent dilatation of the muscle wall were probably the etiological factors.

3. Grünbaum reports 21 cases of complete castration for various reasons, in which the secretion of the mamma occurred in 14 after the operation. Age, climacteric, pathological condition of ovaries, whether a multipara or nullipara, apparently made no difference. In no case of removal of the uterus leaving part of the ovary did the milk secretion start up. The author concludes that secretion of the mamma is dependent upon influences exerted by the ovaries.

5. Hauschild recommends the use of "Euferrol," an iron preparation, each capsule containing 0.012 gr., iron in form of an oxide, and 0.00009 gr., arsenious acid. [L. G. M.]

1. Pringle reports the case of a man, thirty-six years of age, who received a severe blow on the outer side of the knee, knocking it inwards. There was much effusion into

the joint cavity, but the only abnormal motion of the joint demonstrable was in abduction. This was so great that it suggested rupture of the internal lateral ligament. At operation the anterior crucial ligament was found torn from the tibia, taking the spine with it. This was sutured with success. Two years later the knee was functionally perfect, only the very slightest degree of abduction being present, with the knee in full extension. This case adds one more to the three already on record in the literature.

2. Simmons reports two cases: one, a girl thirteen years of age, the other, an infant of ten months. A careful report is given of both cases; the first by x-ray examination, the second by autopsy. The etiology of the condition is still obscure.

3. Buerger brings forward three cases in support of the theory of Garré concerning epithelial cysts. In the course of an injury such as a puncture, the introduction of a foreign body, or a lacerated wound, a portion of the surface epithelium is deposited in the subcutaneous tissues, where it continues to grow, and finally forms a cystic tumor. In the first two cases the cyst was situated on the palmar surface of the tip of the index finger, and followed trauma. In the third case the cyst lay under the skin of the breast near the axillary fold, and no history of trauma was obtainable. The contents of these cysts is of a white pultaceous character.

5. Freeman has devised the following operation for the correction of saddle-nose, by means of a plate: (1) transverse skin incision at the root of the nose. (2) Undermining of skin along bridge and down the sides, by means of a director. (3) Insertion of a stout darning needle from the tip to the root of the nose, to serve as a guide when the plate is pushed into position. The plate should be of celluloid, with carefully smoothed edges, and perforated by numerous holes.

6. Rushmore emphasizes the fact that intussusception being an internal strangulated hernia, operative treatment should be employed immediately. Mechanical agents, such as water or air, should not be used. The mortality in 1892 of 51.7% has been reduced to 12.5% at the present date.

8. MacDonald's patient was forty years of age, and gave a history of a slowly growing abdominal tumor, beginning in the region of the bladder and growing upward, with the gradual onset of pressure symptoms, especially difficult respiration, pain and impaired digestion. The sac was situated in front of the peritoneum, but was surrounded by very firm adhesions. These were broken up with great difficulty, and the cyst removed. In the wall of the cyst were a number of nodules, which proved to be papillomata. An interesting feature in the case was the failure of the peritoneum to absorb a large amount of normal salt solution with which the abdominal cavity had been filled. On the seventh day after the operation the patient presented symptoms of sepsis. The lower end of the wound was opened, allowing the escape of quarts of the salt solution, which had become purulent, and which presented the colon bacillus characteristics. Drainage was continued for a week, after which convalescence and return to health were satisfactory.

10. Russell describes a modification of his original method of operation for the treatment of hypospadias. This method consists of two operations. At the first operation the penis is released and straightened and the glandular portion of the urethra is formed, and lined with preputial skin. At the second operation the perineal and penile portions of the urethra are formed and closed, so as to complete the channel from the perineal opening to the glandular urethra. For this operation suprapubic drainage is employed. A year or more, he states, should be permitted to elapse between the two operations.

[W. C. Q.]

Electrical Excitability of the Motor Nerves. CHVOSTEK (*Wien. klin. Wochenschr.*, No. 26) says that the Erb phenomenon is a constant symptom of tetany in all acute stages. It can always be found, as well as the mechanical irritability, along some motor nerve when sought for persistently and at different times. But often the electrical excitability cannot be obtained a short time after a cramp, or it may show a diminution independently of the other symptoms. The diagnosis of tetany cannot be made with certainty by a moderate grade of the Erb phenomenon, as it is present in healthy individuals in certain conditions. In difficult cases the faradic current in minimal strength may insure the diagnosis by causing an immediate outbreak of tetany.

Experimental Tuberculosis of the Skin in Monkeys. KRAUS and GROSZ (*Wien. klin. Wochenschr.*, No. 26) find that tubercle bacilli from human sources, as well as the bovine type, can produce typical tubercular skin lesions in monkeys. The lesions caused by the human varieties remain centered about the point of scarification, while those originating from the bovine bacillus show progressive infiltration, ulceration and destruction of tissue, often with extension to the internal organs and ultimate death. There is an inverse ratio between the severity of the skin lesion and the number of bacilli visible there in.

Miscellany.

THE DOMESTIC FLY.

THE following deserved editorial condemnation of the common fly, we quote from the New York *Medical Journal:* It is well known to members of the medical profession that the domestic fly is exceedingly active in the transmission of disease, but it is to be feared that the general public has as yet nothing like an adequate appreciation of the fly's pestiferous activity. We are glad, therefore, that at last the lay press has taken the matter up. Last Saturday the New York *Herald* gave its readers an excellent editorial article on the subject. "At no time of the year," says the *Herald*, "is the fly more of a nuisance and a danger than now, and a few mortals there are that may not be persuaded to be his sworn enemy anywhere, everywhere, and every time!"

It is doubtful if the fly is of the least use as a scavenger; he drops his load. Having imbrued his feet in tuberculous sputum or typhoid fever dejecta or some other noisome and revolting material, he makes haste to deposit a part of his spoils on your butter. He is an unclean creature and he spreads the seeds of pestilence. He is far more of a menace to human health than the mosquito, for he has no restricted repertoire. Filth of all sorts is his, and he distributes it industriously; and filth is apt to contain morbific matter. If he would only drown, it would be some consolation, but after prolonged submersion in milk, coffee, or the like he speedily revives and is ready to go at his nefarious work anew, having perhaps in the mean time poisoned the liquid which ought to have done him to death.

It is not alone as a distributor of pathogenic germs that the fly proves inimical to man's health, though doubtless in that capactiy he is the most malignant. By his interference with sleep in the early morning hours he unquestionably exerts a lowering effect on the vitality and renders the organism a readier prey to the germs of infectious disease, besides robbing us of that serenity which is essential to good digestion and to proper dealing with the affairs of life. So far as we can see, the fly is an unmitigated nuisance, and we are ready to join in the cry *delenda est musca.*

RECORD OF MORTALITY

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED AUGUST 21, 1907.

WERTENBAKER, C. P., surgeon. Directed to proceed to Cape Charles Quarantine Station for temporary duty, upon completion of which to rejoin his station in Norfolk, Va.

CLARK, T., passed assistant surgeon. Granted leave of absence for fourteen days from August 26, 1907. August 21, 1907.

KING, W. W., passed assistant surgeon. Relieved from temporary duty at the Hygienic Laboratory, and directed to proceed to San Francisco, Cal., reporting to the medical officer in command, Angel Island Quarantine Station, for duty and assignment to quarters. August 21, 1907.

STANSFIELD, H. A., passed assistant surgeon. Directed to proceed to San Francisco, Cal., reporting to the medical officer in command for special temporary duty. August 17, 1907.

AMESSE, JOHN W., passed assistant surgeon. Relieved from duty at Ellis Island, N. Y., and directed to proceed to Havana, Cuba, for duty in the office of the American consul-general. August 16, 1907.

COLLINS, G. L., assistant surgeon. Granted leave of absence for one day, August 17, 1907. August 16, 1907.

KRULISH, EMIL, assistant surgeon. Directed to proceed to Ellis Island, N. Y., reporting to the chief medical officer for duty. August 15, 1907.

ADAMSON, B. G., acting assistant surgeon. Granted ten days' extension annual leave, on account of sickness, from July 28, 1907. August 8, 1907.

BAILEY, C. W., acting assistant surgeon. Granted leave of absence for ten days from September 16, 1907. August 20, 1907.

HICKS, B. I., acting assistant surgeon. Leave of absence granted Acting Assistant-Surgeon B. I. Hicks for twelve days from August 4, 1907, revoked. August 15, 1907.

RANSOM, S. A., acting assistant surgeon. Transferred from Shanghai, China, to Kobe, Japan, for duty, vice Acting Assistant-Surgeon J. B. Fowler.

ROEHRIG, A.M., pharmacist. Detailed to represent the service at the fifty-fifth annual meeting of the American Pharmaceutical Association, to be held in New York City, September 2–7, 1907. August 20, 1907.

LA GRANGE, J. B., pharmacist. Detailed to represent the Service at the fifty-fifth annual meeting of the American Pharmaceutical Association, to be held in New York City, September 2–7, 1907. August 20, 1907.

ILTIS, G. W., pharmacist. Granted leave of absence for fourteen days from August 17, 1907. August 15, 1907.

BIERMAN, C. H., pharmacist. Granted leave of absence for thirty days from September 9, 1907. August 15, 1907.

RESIGNATIONS.

The resignation of Assistant-Surgeon E. T. Olsen was accepted by the president, effective October 12, 1907. August 15, 1907.

Acting Assistant-Surgeon Linton Turner resigned to take effect August 15, 1907. August 20, 1907.

Pharmacist A. G. Williams resigned to take effect August 31, 1907. August 20, 1907.

BOARDS CONVENED.

The Board convened to meet at Chicago, Ill., July 25, 1907, for the purpose of examining an inspector of immigrants, amended: Passed Assistant-Surgeon B. S. Warren to act in place of Acting Assistant-Surgeon J. J. Gerkins. August 20, 1907.

A board of officers was convened to meet at Galveston, Tex., for the purpose of recommending a site for a national quarantine station. Detail for the Board: Capt. Percy W. Thompson, U. S. R. C. S., Surgeon J. H. White, P. H. and M. H. S., and Capt. J. C. Oakes, corps of engineers, U. S. A. (By authority of Secretary of War.) August 19, 1907.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING AUGUST 31, 1907.

B. H. DORSEY, assistant surgeon. Detached from duty at the Navy Recruiting Station, Des Moines, Iowa, and ordered to Washington, D. C., September 3, for examination for promotion, then to wait orders.

C. M. OMAN, passed assistant surgeon. Detached from the "Arkansas" and ordered to the "Illinois," September 9.

C. H. DELANCY, passed assistant surgeon. Detached from the "Florida" and ordered to the Navy Yard, New York, N. Y.

E. A. VICKERY, assistant surgeon. Detached from the "Illinois" and ordered to the Navy Yard, Boston, Mass.

J. C. MARTIN, pharmacist. Detached from the Naval Dispensary, Washington, D. C., and ordered to the United States Naval Medical School Hospital, Washington, D. C.

L. O. SCHOTKY, pharmacist. Detached from the Naval Hospital, Norfolk, Va., and ordered to the Naval Hospital, Washington, D. C.

C. E. REYNOLDS, pharmacist. Detached from the Naval Medical School Hospital, Washington, D. C., and ordered to the Bureau of Medicine and Surgery, Navy Department.

A. McK. JONES, acting assistant surgeon. Sick leave revoked; ordered to the Naval Recruiting Station, Des Moines, Iowa.

RECENT DEATHS.

DR. JOSEPH A. WINKLER, of Jamaica Plain, died last week at the age of seventy-seven. He was born in Savannah, Ga., studied medicine in New York and for the greater part of his life was a practitioner in Jamaica Plain.

DR. WILLIAM E. JOHNSON, for many years a practising physician at Keyport, Monmouth County, N. J., died at his home in Ontario, Canada, August 27.

DR. EDWARD J. MESSEMER, of New York, while abroad for the summer, died at Marburgh, Germany, on August 5. He was sixty years of age, and was graduated from the medical department of the University of the City of New York in 1871. He devoted himself more particularly to neurology, and at the time of his death was one of the physicians to the out-patient department of Mount Sinai Hospital.

DR. GEORGE WALDRON, a prominent physician of Rochester, N. Y., was instantly killed on August 28 in an accident, at Hopewell, near Canandaigua, in which his automobile was struck by a trolley car. Three aged women to whom he was giving a fresh air outing in his large touring car were also killed by the collision. Dr. Waldron was sixty-two years of age and was graduated from the medical department of the University of Buffalo in 1881.

THE OPERATIVE TREATMENT OF VARICOSE VEINS OF THE LOWER EXTREMITY.*

BY JOHN T. BOTTOMLEY, M.D., BOSTON.

NOT alone to the greater ills and affections that in themselves endanger human life should our professional care and attention be directed; the lesser ailments, rarely fatal but frequently disabling, call for relief and justly claim their due share of our notice. It is with this thought in mind that I bring to your attention in this paper the subject of varicose veins of the leg. I need make no apology, I trust, for my choice of topic. Recognized for centuries, widespread in its field, frequently crippling in its effects, attacking most often the wage-earning class,—this affection of the venous system is worthy of our best endeavors for its relief. Its treatment usually falls within the province of surgery, and it is through operative procedures alone that permanent and satisfactory results can be obtained in the very large majority of cases.

No lengthy discussion of the subject will be undertaken, but it may not be amiss to recall a few important facts with regard to the anatomy, etiology, symptoms and pathology of the affection before taking up the operative treatment.

There are two systems of veins in the lower extremity. In the leg each main artery has two accompanying veins which unite at the lower border of the popliteal space to form the popliteal vein; the latter in its turn becomes the femoral.

The internal and external saphenous veins with their branches form the superficial system. A detailed description is unnecessary. It is important to note that the internal saphenous has free communication with the deep system through the deep fascia. It also communicates freely with the external saphenous in the foot and leg. The external saphenous has but one important branch; it is given off just before the parent vein empties into the popliteal and, after turning around the inner border of the thigh, anastomoses with a large branch of the internal saphenous to form a well-marked connection between the two larger veins. It frequently shows a varicose condition.

The external saphenous has from six to twelve valves, and the internal from eight to twenty. This is a most important arrangement. Under normal conditions the blood pressure in the veins is distributed in such a way that at any given point of the vein wall the pressure is only that caused by the weight of the blood column between it and the next higher valve. With incompetent valves the story is quite different. Above Poupart's ligament there is no valve in the femoral, external iliac or inferior cava veins; hence there is nothing to prevent the pressure of the blood in these vessels from being communicated to the internal saphenous, and the latter must sustain the weight of the blood column between itself and the heart. This is a relatively small matter, when the valves of the vein are for any reason incompetent.

The etiology of varicose veins is obscure. Most of the so-called causes are really neither primary nor originating; they are simply exciting or aggravating agents. Many cases, indeed, are seen in which are present none of the conditions ordinarily mentioned as causes. The affection, as seen in our out-patient clinics, is most common in patients in the third and fourth decades of life. It must be remembered, however, that these patients seek aid not at the first appearance of symptoms, not when the varicose condition is first noticed, but only when it becomes troublesome. Kennedy [1] in his report of 27 cases informs us that in no fewer than 6 the varicosity appeared at the age of ten or earlier, and that in 11 cases it was noticed between the tenth and the twentieth years. Such facts give credibility to the opinion of Bennett,[2] who calls attention to the frequent early appearance of the condition and maintains that the most probable cause is a congenital defect by reason of which the valves are not normally competent; this incompetency of the valves, says Schambacher,[3] exists because of congenital weakness of the vessel wall, due to their regular development and arrangement of its elastic and muscular elements. The probability of a congenital etiological factor is further increased by the fact that the condition may exist in both extremities at the same time or in either alone. Of 864 cases, including those of Bennett, Miller, Goerlich and the Carney Hospital series, both extremities were affected in 414, the left alone in 252, and the right alone in 198. Heredity, too, is said to have an etiological influence. There is, moreover, a relatively small group of cases — the "inflammatory" of Miller,[4] — in which a pretty definite relation can be established between the varicose condition and a preceding phlebitis, consequent upon pregnancy, typhoid, erysipelas, pneumonia, etc. Of Miller's 128 cases 40 are classified under this head. Trauma is unquestionably a frequent, exciting cause.

Little need be said of the pathology. As we see the cases, the gross pathology is usually evident. The fundamental pathology rests on the facts that, whatever the cause may be, there exists stasis in the veins of the lower extremity, that the valves are incompetent, and that the veins most often affected run in the subcutaneous fat where there is but little resistance offered to their dilatation. With the late pathology, the simple phlebitis, the organized phlebitis, the periphlebitis, the ulceration, the eczema, etc., we are all familiar.

The symptoms vary in severity. Some cases are subjectively symptomless; in many, on the other hand, the symptoms are so severe as to seriously cripple or even incapacitate the patient; the former seldom present themselves for treatment; of the latter, many examples are seen.

What does surgery of the present day offer in the way of radical treatment? How much hope of permanent cure can we promise these cases? Though numerous operative procedures have been

* Read before The Massachusetts Medical Society, June 11, 1907.

proposed for its relief, those in use to-day have as their foundations one of the following methods: (1) The Trendelenburg, (2) the Schede, or (3) the Madelung. These operations, modified or combined, are conceded to be the most effective of all.

1. Trendelenburg [5] in 1890 published his method of division of the internal saphenous between ligatures close to the saphenous opening. This prevents the transmission of the weight of the blood column in the femoral, iliac and inferior cava veins down to the internal saphenous with its incompetent valves. The procedure has been modified, and now excision of about two inches of the vein is practised instead of simple ligation. While there can be no doubt that in many, especially the early, cases, his method gave good results, yet recurrences have been reported in percentages varying from 6% (Remedi) [6] to 15 % (Faiszt) [6] and even 22% (Perthes).[6] Miller,[4] from a study of reported cases and of the Johns Hopkins Hospital series, concludes that the cures average about 75%. The percentage of recurrences increases with the length of time after operation, rising in the Johns Hopkins Hospital series from 11% to 37% from the fourth to the eighth year.

2. In the Schede [7] operation all veins superficial to the fascia are divided between ligatures, through an incision encircling the leg in its upper third. Von Wenzel,[6] a former pupil of Trendelenburg, modified the procedure by making a similar incision at the junction of the middle and lower thirds of the thigh and dividing the superficial veins at that level. A " horse-shoe " incision has also been used in place of the complete encircling incision. These operations attempt to attain their objects by forcing the blood to get out of the leg into the femoral vein by the way of the deep venous channels lying under the fascia. In a small series of 9 cases at Johns Hopkins, 67% had recurred at the end of ten years.

3. Madelung,[8] through a long incision from which the skin is turned back a hand's breadth on either side, excises practically the entire internal saphenous vein and a portion of its branches. Many modifications of this method have been offered, the chief ones being subcutaneous extirpation of the vein or excision of small portions throughout its length. Ninety per cent of cures is claimed for it.

The Trendelenburg operation is easy of performance and practically free from danger. But often it does not fulfill the conditions necessary for a radical cure. Two factors militate against its success and, in a way, against that of the Schede method. (*a*) First, the internal saphenous vein has free communication with the deep system and also with the external saphenous. This communication may play an important part in the prevention of a cure; for Bennett believes that varicosity, stasis, and consequent increased pressure in the deep veins, often coexists with a like condition in the superficial. It is evident that frequently in the Trendelenburg operation no barrier is offered to the transmission of this increased pressure and its effects to the superficial veins. In fact, consequent to this operation, enlarged veins either appear or, if present at the time, increase in size. We have noted that, even after extensive extirpating operations, some of the venous branches which were not removed have later become enlarged; this enlargement could take place only because of back pressure from the deep circulation. (*b*) The second factor in recurrence is that restoration of the superficial venous circulation sometimes takes place after ligation. (Miller,[4] Ledderhose,[9] Goerlich.[10]) This may occur in three ways: (1) by anastomosis around the scar, (2) by formation of varices in the scar, or (3) by union of the ligated stumps with formation of an intact vein. This is an interesting phase of the subject, but we cannot discuss it in a paper of this length.

Occasionally, though rarely, gangrene of the foot may follow the Schede procedure. Much more common sequelæ are edema of the leg and either hyperesthesia or anesthesia (more frequent) below the scar because of section of the subcutaneous nerves. Von Wenzel [6] claims that his operation is followed by no such ill results. In 3 cases reported by Georgi,[6] no anesthesia appeared, despite the fact that in all 3 operations he saw and preserved just one nerve filament. We have had no experience with the method, but beyond the fact that it shuts off the superficial venous circulation at a higher level than does the Schede, it seems to have nothing to recommend it over the latter.

The unmodified Madelung operation is seldom if ever done now. The long disfiguring scar and the extensive subcutaneous area necessarily exposed to the chance of infection were potent factors against it. But its principle is still effective and we believe that this operation, as modified by C. H. Mayo,[11] is the best single operation of the present time for varicose veins. This does not mean that the modified operation can be applied successfully to every case. On the contrary, there are many cases in which mere extirpation of the internal saphenous vein will not give a perfect cure; but it is nevertheless true that such extirpation must be the essential part of any successful operation for the relief of the condition.

As a preliminary step to any operation that has for its object the transference of the venous circulation from the superficial to the deep veins, it must be definitely established that there is neither thrombosis of the deep veins nor any marked impediment to the return of the blood through them. A history of a severe preceding phlebitis should arouse our suspicions. Mayo has adopted the diagnostic expedient of having doubtful cases wear an elastic stocking, or a bandage from the toes to the knee for a week. If this gives comfort to the patient and relieves the symptoms, it is assumed that the deep veins are sufficiently patent and the following operation is usually done:

The leg is held in an elevated and extended position by means of an ankle-support which is attached to an ordinary, upright, gynecological

standard. This position serves a double purpose; it checks hemorrhage and renders more accessible the field of operation. The internal saphenous is then divided between hemostats in the upper third of the thigh. The proximal end is ligated; the distal end is threaded into the ring of the enucleator and again grasped with a hemostat. The vein, put under moderate tension by a pull on the hemostat, is then extirpated subcutaneously by pushing the enucleator in the direction of the knee. When six to eight inches of the vein has thus been freed, the ring is pushed up against the skin from beneath, a short incision made down on to it, the vein grasped, the enucleator withdrawn, the freed length of vein pulled out through the short incision, rethreaded into the ring, and another length is then extirpated in a similar manner. This process is repeated until the vein has been removed down to a point four to six inches below the knee. The lateral branches are torn as met and usually do not bleed. Occasionally, however, there may be bothersome hemorrhage; this can be controlled by pressure with a gauze pad or by light tamponing of the incision from which it comes. If the main trunk breaks during the manipulation, pressure is applied over the point of rupture, a short incision is made lower down over the vein, the vessel divided between hemostats and extirpated from below upwards to the point of rupture. As a substitute for the enucleator, long forceps which form a ring at the end when closed are sometimes used. Occasionally torsion is employed for removing portions of veins, especially when we are dealing with branches. The external saphenous, when varicose, is also extirpated.

At the Carney Hospital my colleague, Dr. Munro, and I have operated on 57 cases of varicose veins in the last three and a half years. The method described above has been approximately the method used in the great majority of cases. Our experience has emphasized several features which, though unessential, are nevertheless worthy of note. We extirpate the internal saphenous to as low a level as possible. Mayo writes that his method is not always applicable, and that in about 10% of the cases either extirpation by the open method or subcutaneous extirpation by some other form of blunt dissection must be substituted for it. We have been led to the conclusion that such substitution must be made in considerably more than 10% of the cases. When the veins are brittle, when they are unusually thin, when the subject is very fat, when the veins are very large and thrombotic, when a considerable degree of periphlebitis is present, or when calcareous deposits have formed, the enucleator does not work well. However, we have yet to see the case in which at some stage of the operation the enucleator has not been of some service. In general, the instrument is more effective in the thigh than below the knee. In a considerable number of cases, especially when the veins are enlarged, thickened and thrombotic, the index finger has proved to be a very efficacious instrument for subcutaneous extirpation.

We have also found it wise, when a branch cannot be torn with the use of moderate force, to make a short incision down on to the enucleator at the point where the branch joins the main trunk, to unthread the latter and, after extirpating the branch as far as can be easily done, to ligate it and then to proceed with the removal of the main vessel. We make a point of ligating the main trunk very close to the saphenous opening and of tying any large branches entering the internal saphenous in the neighborhood.

Any mass of varicose veins, wherever in the lower extremity it may be located, is dissected free and removed. Usually such masses can be removed only through a moderately long incision. Portions of visibly enlarged veins in the leg other than the internal saphenous are also removed, even though at the time they may not show a varicose condition. If there are numerous visible venous channels coursing up the leg, even though the enlargement be only moderate, a partial Schede is done in addition to the usual operation; that is, a " horse-shoe " incision is made, extending perhaps half way around the leg in the upper third, and all superficial veins exposed by the incision are divided between ligatures. All this, of course, takes additional time, but we believe that it is time well spent. Following Mayo's advice, we avoid making incisions in and very close to the fold of the knee, because of the danger of keloid formation in that locality.

All incisions are closed by lock sutures of horsehair and covered with collodion dressings. It is our practice to close the incision through which the internal saphenous is first tied just as soon as the first length of vein has been extirpated. This lessens the chance of infection. Ulcers are either excised and skin grafted or thoroughly curetted and allowed to heal by granulation. Mayo [11] describes an ingenious way of dressing these ulcers and grafts so that their progress may be observed without disturbing the dressing of the whole limb. Eczematous areas are painted with compound tincture of benzoin. Superficial abrasions are wiped with tincture of iodine before proceeding with the operation. Finally, the lower extremity is wrapped in gauze, a bandage is applied from the toes to the groin and around the abdomen in the form of a spica; the patient is put to bed with the leg elevated on a pillow. The duration of the stay in bed averages about two weeks. After leaving the hospital the patient usually wears a bandage from toes to knee three to four months.

The gist of the whole matter is that, while removal of the major portion of the internal saphenous vein is the essential part of the operation, other procedures must be added suited to the conditions of each case.

Subcutaneous extirpation is by no means a recent operation. Narath [12] gives a most interesting historical account of the various operative procedures for the treatment of varicose veins. Subcutaneous extirpation was first described by Oribasius (325–403 A.D.). It is thus about fifteen hundred years old. It fell into disuse in the later

Middle Ages and was revived again after the advent of antisepsis.

The operation is not entirely without danger. Embolism, particularly of the lungs, has followed it several times. Goerlich [10] mentions 6 cases: Miller [4] describes a probable case occurring in the Johns Hopkins series, and mentions another reported by Sylvester. It has followed both simple and extensive operations, but fortunately is very rare. As yet, we have not met with it at the Carney. The other danger is sepsis. Some degree of it is difficult to avoid because of the presence of eczema or ulceration in many of the cases. We have once seen severe, post-operative erysipelatous inflammation of the leg. Fortunately it was not fatal, but the patient was seriously ill for some days.

In our series of 57 cases we have done the so-called Mayo operation 46 times. We know the present condition in 28 of these patients; 24 of them are perfectly well; in 3 the result is fair and can, I think, be made perfect by extirpation of some of the smaller veins which, though not particularly enlarged at the time of operation, have become so in the meantime. The fact that this post-operative enlargement has occurred in these smaller veins has caused us to become more and more radical in our primary operative procedures and to make them more extensive.

Our only really poor result is in a woman who now has a rather marked edema and more or less constant dull pain in both legs. We believe the failure in this case to be due to the fact that we operated before we were certain that there was no obstruction to the return of the blood in the deep veins; for there can be no doubt that in this case there was and is a partially obstructed deep venous circulation. With our present knowledge operation would not have been advised.

We have done the Trendelenburg operation, modified and unmodified, in 12 instances. Of the 6 patients whose present condition we know, 3 are well; 3 others showed recurrence, 2 of whom have been cured by the modified Mayo procedure.

We have done the Schede operation twice and excision of portions of the internal saphenous twice. The post-operative history of these cases is unknown to us.

As we have previously stated, recurrences are said to increase in number as the post-operative period lengthens in duration. This applied, however, only to the result of the Trendelenburg and Schede operations. With us so-called recurrences after the Mayo operation, when they have come at all, have appeared within the first six months of the post-operative period. Of course, our work has covered a period of only three and a half years, and it may be said that so short a lapse of time does not permit of our speaking of results with definite assurance; but we believe that after the operation as we now practise it a recurrence, as such, cannot take place. Some of the remaining branches may enlarge and, perhaps, even become varicose, but re-establishment of the superficial venous circulation is impossible. We feel that, in properly selected cases, both a subjective and an objective cure may be promised in practically all instances, and that examining surgeons for police and fire boards can now have no sound reason for rejecting as candidates, for either the police or fire departments, men who have undergone operation for varicose veins and remain well for a year thereafter.

To sum up in brief:

1. The important etiological factor is a congenital one; in a small proportion of cases it is inflammatory.

2. The operation that will give the best results must have as its essential feature extirpation of the internal saphenous vein; but to this such other procedures must be added as are suitable to each individual case.

3. Before operative measures are undertaken it must be demonstrated that the deep venous circulation of the lower extemity is not obstructed to any marked degree.

4. In properly selected cases it is believed that a permanent cure may be promised.

5. The operation is almost but not entirely free from danger.

DISCUSSION.

DR. G. H. MONKS, of Boston: The subject has been so thoroughly presented by Dr. Bottomley that little remains to be added. The number of cases of varicose veins which come to operation is constantly increasing. Whereas years ago comparatively few cases were submitted to operation, at the present time cases of varicose veins form an appreciable proportion of the total number of operations in a general surgical clinic. This, of course, is for the reason that, by improved technique, including among other things a more extensive removal of the veins than was formerly practised, surgeons are getting better and better results and the cases where operation is contra-indicated are getting fewer and fewer.

I quite agree with Dr. Bottomley that the best single operation of the three of which he has spoken is the Madelung operation, or one of its modifications; it has been so satisfactory to me that I have used it exclusively in the 26 cases which I found after a rather hasty search through my records. The other two operations, the Trendelenburg and the Schede,do not appeal to me. I might think differently should I use them, but, to my mind, the Trendelenburg does not seem radical enough, and the Schede runs too much risk of being followed by unpleasant results caused by division of the veins.

I think it is well to emphasize the importance, on account of its probably lessening the danger of embolism, of working from above downwards rather than in the opposite direction. This method of procedure has also the advantage of enabling the operator to dissect the various branches most effectively.

Dr. Bottomley should be thanked for having brought to the notice of the profession this report which shows

how much can be accomplished by means of the latest methods of operating.

Dr. J. B. Blake, of Boston: There are two aspects of the operation for varicose veins, which are worthy of a few words. Although the operation seems to be one of the simplest in surgery, its field being superficial to the deep fascia, it is nevertheless not without its dangers. Of these sepsis is the most important, and it may be so severe as not only to ruin the operative result, but also endanger the patient's life. Simple though the operation is, the patient's general condition must be considered just as thoroughly as the local lesion. Failure to include this element of risk was, I believe, the determining factor in the following case, the only fatal outcome of an operation for the relief of varicose veins that is recorded in Boston. The patient was an old, feeble woman, operated on by a young doctor who had recently finished the duties of surgical house officer in a Boston hospital. There was an open ulcer, as well as an extreme degree of varicosity, threatening rupture and hemorrhage. The operation was a local dissection. Immediate phlebitis supervened; the patient was sent to a hospital, where in spite of every effort, toxemia and death followed within a week. Aseptic precautions were taken at the time of operation as a matter of course, but the patient was operated on in her own home. A longer preparation, increased attention to improving her general condition, would undoubtedly have averted this disaster. It seems worth while drawing attention to this single case, as at present every one seems to be doing surgery, at all times, under all conditions and upon all sorts of surgical risks. Necessarily, some patients suffer, and from causes that are not legitimately essential to modern surgery.

The other aspect of the operation is the precise reverse of the foregoing: in patients whose general condition is satisfactory, but who have large and slowly healing chronic ulcers, it is not always necessary to postpone the operation until these ulcers heal, even though a considerable portion of the operative field lies in immediate proximity to the ulcer. If unusual care is taken in cleansing the skin, and the ulcer be entirely and permanently shut off from the rest of the leg by a special dressing, applied before the anesthetic is administered, and later covered by the sterile sheets, the operation may proceed to within one centimeter of this dressing with perfect safety. This is, of course, intended to apply only to patients in hospitals, or under ideal home conditions; but both Drs. Cotton and Blake have had several such cases in the past two years, in which the operative result was as good as if no ulcer was present. As a rule, the ulcer heals more rapidly after the operation.

RECTAL ANESTHESIA.

BY JOHN H. CUNNINGHAM, JR., M.D.,
Surgeon, Long Island Hospital, Boston, Mass.

The frequent inquiries regarding the method of rectal anesthesia since its demonstration at the meeting of The American Medical Association, June, 1906, leads to a further report upon the subject.

Since the first publication [1] the method has been more thoroughly tried, and while the general conclusions drawn at that time remain the same, experience has established certain new features. It is not my desire to give detailed reports of cases which have done well, but rather to refer to the technique, mention the cases of special significance and to refer to the work of other men whom I happen to know have used the method and to express their impressions. The following details of technique were published in the original article:

History. — The first mention of producing ether narcosis by the rectum appears in Pirogoff's book on etherization, published in 1847 in St. Petersburg. About the same time Roux [2] made experiments upon the subject, as did Vincente y' Yhedo and Marc Duprey, employing injections of ether pure and mixed with water. Their observations, although demonstrating the practicability of this method of producing complete anesthesia, excited little interest.

No mention of the practice appears again until 1884, when Molliere,[3] following the suggestion of Dr. Alex Yversen, of Copenhagen, employed the method at l'Hôtel Dieu de Lyon and established its merit. His experiments were made with a simple apparatus similar to that employed by the earlier investigators. It consisted of a large bottle almost filled with ether from which a tube conducted the vapor to the rectum. The bottle was placed in a water bath which had a temperature greater than the boiling point of ether. By this means the ether was made to boil, and by its own volatile expansion was carried over into the rectum. Molliere produced complete anesthesia in from ten to twenty minutes, and used only a small quantity of ether (10 gm.) in so doing. Unlike the results of Pirogoff's and Roux's experiments, those of Molliere created considerable interest, and several surgeons practised the method with variable results.

Hunter [4] reports six cases which he summarizes as follows: "The method in question promises, in my opinion, to effect a radical improvement in the method of administering ether. A striking feature is the small quantity of ether required, showing how large a quantity is commonly wasted. The absence of any unpleasant sensations on the part of the patient is a matter of no small importance. The rapidity with which anesthesia can be induced and the general absence of struggling and opposition by the patient give the rectal method a decided value, even if it should be used only as a preliminary step to the usual method." Hunter makes no reference to diarrhea or other ill effects being produced by the employment of this method.

Weir [5] mentions seven cases where rectal etherization was employed by Dr. William T. Bull with the result that nearly all had bloody or simple diarrhea following, and that one case became collapsed afterward. He also cites two cases of his own. One was a boy fourteen years of age who received rectal ether for fifteen minutes, and although he became sleepy and the breathing stertorous, sensibility was not completely lost and etherization in the ordinary way became necessary. His other case was a robust child of eight months, upon which he operated

for hare lip. The child was fully anesthetized in three minutes and the operation completed successfully. The amount of ether used was in all less than two ounces. The child was "somewhat depressed" at the end of the operation, but rallied under stimulation and heat. During the night it had several bloody movements and died the following morning.

Wanscher [6] records twenty-two cases anesthetized by injecting ether vapor into the rectum after the method suggested by Pirogoff, and speaks in most favorable terms regarding his results. He mentions one especially noteworthy case which explains the occasional difficulty in producing narcosis by the rectal method. In this case he gave rectal ether for between thirty and forty-five minutes with no result. Knowing that the patient's bowels had not been properly cleaned out he postponed the operation, emptied the bowel and rectum of its contents and the following day repeated the etherization. The patient was completely etherized in thirteen minutes. There are several cases in our series that corroborate this observation, and it might be said that difficulties in rectal etherization arise only from failure to have the bowel clean.

Post,[7] reports three cases etherized at the Boston City Hospital by the rectal method. The first case was a man with cellulitis of the arm, with general toxic symptoms. He was completely anesthetized in thirteen and a half minutes. The ether was then discontinued and complete anesthesia continued for nearly a half hour. Several hours later he had two loose movements which contained much gas. A starch and opium enema was given and no further diarrhea resulted. The second case was one which came to the hospital after having eaten a hearty breakfast. The patient received rectal ether for thirty-four minutes, at which time she was completely anesthetized, one and three quarters ounces of ether being used. During the etherization the abdomen became slightly distended and the gas was expelled by abdominal pressure. The patient vomited about an ounce of fluid once, following the ether. There was a normal movement from the bowel about one hour later and subsequently two slightly loose movements, one of which was tinged with blood. The third case was one with hemorrhoids. Etherization was complete in fifteen minutes and a little less than two ounces of ether was used. There was no vomiting or diarrhea following the etherization.

Hewett, in his book, "Anesthetics and Their Uses," 1901, speaks of the early work of Alex Yversen and Molliere and the cases of Weir and Bull. He mentions Dr. Buxton's preference for rectal etherization in operations upon the upper extremity. He makes no statement that leads one to believe that he has had any personal experience with this method of ether administration.

Buxton, in his book on "Anesthetics," 1900, states that he has employed the method "pretty extensively," and strongly advocates its use in operations about the head and neck and for empyema.

Advantages. — It is obvious that a free and continuous access to the field of operation is a great advantage to the surgeon. In operations upon the head, face, mouth, nose, throat, ear, eye and neck the absence of the ether cone not only lessens the technical difficulties of the operation, but also minimizes the chances of sepsis and lessens considerably the time necessary to perform the operation.

Experience has shown that the patient passes under the influence of the drug rapidly and with no sense of suffocation; that less ether is used, not only in producing the narcosis, but also in maintaining it; that the stage of excitement is lessened or absent; that the ether recovery is more rapid, and that the disagreeable after-effects of inhalation ether narcosis are diminished or absent. It is also noteworthy that alcoholics pass through the stage of excitement with little, if any, resistance or struggling.

The employment of this method of etherization in diseases of the lungs, especially tuberculosis, abscess and pneumonia, immediately suggests itself. The same might also be said of empyema, mediastinal abscesses and new growths.

Although it is true that the greater part of the ether is eliminated through the lungs as in inhalation narcosis, the direct irritation of the concentrated vapor is overcome, and post-operative pneumonia should be lessened.

The absence of bronchial secretions in the cases has been a striking feature.

As has already been pointed out by Dr. Wanscher, the patients that have taken ether by inhalation and by rectum express a preference for the rectal method, the chief explanation being that the convalescence is easier.

Disadvantages. — To say that this method has no disadvantages in view of the fact that it has lain idle for a period of twenty years seems startling. By the old method of administration there were distinct disadvantages which warranted the discarding of this method of ether administration. These were rectal disturbances, and the inability to control the stages of narcosis.

It has been claimed by some that ether narcosis by rectum produces diarrhea and melena. This may be easily explained when we consider the old method of administration, which was to place a bottle of ether in a boiling water bath and allow the vapor to be carried over into the rectum by its own expansion. By this method there was no means of appreciating the amount of ether passing into the rectum, and the ether going over at a high temperature was condensed in the tube and rectum.

To overcome these two objectionable features, the illustrated apparatus has been employed. In my own series of cases there has been no diarrhea or bloody stools, the bowels being rather constipated than otherwise. In those patients who were properly prepared the bowels have moved for the first time on the third to the fifth day. It has been suggested that this absence of rectal

[6] Cong. Internat. Med. Sciences, 1884, ii, p. 186, sect. 1.
[7] BOST. MED. AND SURG. JOUR., 1884, cx, p. 442.

irritation may be due to the better quality of ether now in use, as well as to our method of administration.

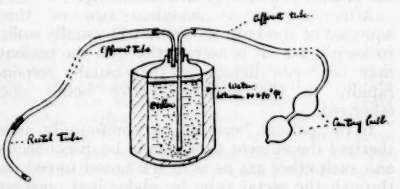
Colicky pains and painful distention mentioned by Buxton as after-effects have been noted in a few cases. Pain has been so slight and has passed off in so short a time that it can hardly be considered a disadvantage. This pain has been noted more particularly in those cases not properly prepared.

It is not desirable to employ this method in abdominal cases on account of the distention, but there seems to be no reason why it should not be employed to produce narcosis preliminary to the administration of ether by mouth, especially if the patient is known to take ether badly.

Technique. — To obtain the best results it is essential that the bowels should be thoroughly cleaned out. It has been our custom to give two ounces of a saturated solution of magnesium sulphate on the evening before operation, and early the following morning a large suds enema. Just before going to the operating table another similar enema is given.

The ether breakfast has consisted of two ounces of beef tea.

Apparatus. — We began our experiments with a wash-bottle six inches in height and two and a half inches in diameter. Of the height four inches was used for ether space and two inches for vapor space. A simple straight glass tube led to the bottom of the bottle and was connected with the afferent tube. The efferent tube, leading to the rectum is connected with a glass tube, the proximal end of which was flush with the inner surface of the rubber stopper. This was a satisfactory apparatus except that the bottle did not hold enough ether without refilling during a long operation. Later, we tried an apparatus in which the wash-bottle was twelve inches in height and one and a half inches in diameter, allowing a nine-inch column of ether for the bubbles to ascend through. This was discarded as it was difficult to keep the apparatus right side up, and the small amount of ether used rapidly cut down the height of the column, owing to its small diameter.



Later the Davidson apparatus, which is used to administer warm ether vapor through a hard rubber tube in the corner of the mouth, was tried, being attached to the rectal tube, and was discarded because of the foot pump and the stop-valve in the efferent tube, the foot-pump filling the bag which caused a constant flow of ether when the stop-valve was opened. In administering the anesthetic in this way it is impossible to appreciate as accurately the amount of ether being given as with the bulb method about to be described.

The apparatus which we have used on all our later cases and which has been the most satisfactory consists of a bottle, the body of which is seven and a half inches in height, five inches being used for ether space, two and a half inches and the neck for vapor space. The diameter is four inches and the capacity on the ether space twenty-nine ounces, so that a large amount of ether may be used without materially lowering the ether column. The afferent tube which leads to the bottom of the ether column ends in a bulb with several small perforations so that the air ascends in several small bubbles. The stopper and the connections should be tight.

The bottle is placed in a water bath at a temperature of between 80° and 90° F. Ether boils at 98.6° F. It is desirable to keep the temperature below this point. By keeping the ether as warm as possible without boiling, the air forced in by the bulb is more easily saturated. If the operation is a long one it may be desirable to renew the temperature of the bath. We have employed all makes of ether and the results have been the same. The inexpensive ether has been quite as satisfactory as the most expensive.

The efferent tube should be sufficiently long to allow moving the wash-bottle away in case the operator wishes to change his position from one side of the table to the other. We have tried efferent tubes of varying lengths and have noticed no difference in the results; ether in no case being condensed in the efferent tube.

The afferent tube should be of sufficient length to allow the etherizer to inspect the patient from head to foot still retaining the bulb in hand. We have not found it necessary to employ an "interseptor" as no ether is condensed in the tube.

We have tried rectal tubes with eyes placed at various intervals; but these have had no advantage over the stiff rectal tube with a single eye at the end, and do have the disadvantage of kinking more easily on account of the eyes weakening the tube.

Administration. — The patient lies upon the back with the legs held in slight flexion by a sandbag placed under the thigh. A stiff, large-sized catheter or rectal tube is inserted into the rectum for a distance of from ten to fourteen inches. When there is difficulty in placing the tube because of kinking a bougie is introduced into the tube and withdrawn after the tube is in place. The efferent tube is now connected with the rectal tube and the vapor forced in until considerable gas is pressed around the rectal tube. Keeping the forefinger in the rectum beside the tube, unless it causes the patient pain, hastens the expulsion of the rectal gases.

It is essential that the rectum be distended to the point of emptying itself around the tube, for we have learned that without first removing the

gas normally in the bowel the patient absorbs the ether much more slowly, presumably because of the dilution of the ether gas by the gases normally in the gut. After this gas has been expelled the ether should be forced in by a few squeezes of the bulb every five or ten seconds, or until it is expelled about the tube. A little experience with the method will enable one to keep the proper amount of ether gas in the rectum without its being expelled around the tube.

At the first introduction of the rectal tube, or the first volume of ether, the patient may feel a natural discomfort and desire to defecate; but in a short time this sensation disappears. The breath becomes ether laden in from one to five minutes after the ether is started. The patient gradually becomes drowsy, the breathing stertorous and he then passes into complete surgical narcosis without any stage of excitement.

Narcosis being complete, the same signs regarding the patient's condition should guide the anesthetist as in administering ether by inhalation.

Care should be exercised after complete narcosis has taken place to see that the jaw does not drop down allowing the tongue to fall back over the larynx. In one of our early cases the patient became partially asphyxiated through neglecting this precaution. When the jaw was drawn forward the natural color returned to the face and the patient began to breathe normally.

After narcosis is complete two or three squeezes of the bulb a minute will usually suffice to keep it so. It is noteworthy that the patients may be "run light," as they usually respond rapidly to the injections after being once etherized.

If the patient becomes too profoundly anesthetized the efferent tube should be disconnected and such ether gas as is in the bowel forced out through the rectal tube by abdominal massage. An oxygen tank should be connected with the rectal tube and this gas made to distend the bowel. Artificial respiration and stimulation should be resorted to in the usual manner. When the operation is complete it has been our custom to expel as much of the gas ether as possible by massage of the abdomen with the rectal tube still in position.

POINTS OF INTEREST REGARDING THE METHOD.

Briefly summarized, the points of interest are as follows: There is comparatively little ether used. There is no stage of excitement. Vomiting seldom occurs. Bronchial secretions are absent. There is a comparatively quick ether recovery. The bowels are slightly constipated. Unless the bowel is free from feces it is difficult to produce narcosis.

Before considering these points in detail it is necessary to allude to the law of partial tension, upon which the physiology of ether narcosis is based.

The law of partial tension. — When ether or almost any other gas (excepting oxygen) is inhaled, it passes through the walls of the alveoli into the blood circulation until the blood circulation contains the same quantity of the gas as the air in the alveoli. When the percentage of the gas is decreased in the air of the alveoli by respiration, then the gas will pass back from the blood into the air in the alveoli until the air of the alveoli contains the same percentage of the gas as the blood.

The physiology of ether narcosis by rectal administration. — There is no reason to believe that the law of partial tension holds true when ether is administered by the rectum, nor is there any known scientific explanation of the phenomenon of ether narcosis produced by this method of administration.

A theory advanced by Dr. M. Vejux-Tyrode, of the Pharmacological Department of the Harvard Medical School, who was kind enough to study our cases, is briefly as follows:

First, a definite per cent of ether must be present in the entire circulation to produce complete surgical anesthesia. In human beings this amounts to a little under six volumes per cent. The rapidity with which complete narcosis results depends upon the rapidity with which the percentage of ether is brought up to nearly six volumes per cent. When ether is given by the lungs in the form of vapors it can only be administered in great dilution unless excretion be interfered with, and the percentage in the blood be raised above six volumes per cent, which would prove fatal by paralysis of the respiratory center in the medulla. On the other hand, when ether is administered by the rectum as a vapor, concentrated vapors may be given. Therefore, the chances for the rapidity of absorption and the raising of the required six volumes per cent will take place more rapidly while excretion may take place freely from the lungs.

This is an explanation for the rapidity with which certain of our cases have become anesthetized.

Fatality is less likely to result as the lung is free to eliminate ether as fast as it is absorbed from the rectum.

The fact that comparatively little ether is used in producing and maintaining anesthesia by the rectal method is evident when we realize that all the ether used is absorbed.

There is no stage of excitement, because of the rapidity with which the patient passes through the first stage of ether narcosis. We know, of course, that the absorption of ether at first depresses the co-ordination centers of the cerebrum, next the other parts of the cerebrum, consciousness and sensibility to pain, which takes place simultaneously with paralysis of the cord. This latter stage is that of surgical narcosis. The third stage, the undesirable one, is paralysis of the respiratory and vasomotor centers in the medulla. This does not seem to take place, probably because the lung acts as a safety-valve, preventing the raising of the amount of ether in the blood to six volumes per cent.

Vomiting has occurred in a few cases, but has been infrequent and has occurred chiefly in those cases who received ether by mouth preliminary to the rectal method. The patients who have vomited have done so but once or twice, and individuals who have had much vomiting following inhalation narcosis have vomited but once or twice or not at all.

There are two theories offered to explain the vomiting which usually follows ether narcosis. One, stimulation of the vomiting center, just as with apomorphine. The other, a reflex stimulation due to the local irritant action of the swallowed ether-laden saliva on the mucosa of the stomach.

Our experiments are rather in favor of the latter theory because we obviate to a considerable extent the swallowing of ether-laden saliva, and the cases etherized entirely by the rectal method failed in the great majority of cases to show vomiting as an after-effect. If the former theory were true there is no reason to expect any difference in the amount of vomiting between the two methods of administration, as the same amount of ether must necessarily reach the central nervous system.

The increased amount of *secretions* by inhalation narcosis takes place from local irritation to the upper respiratory air passages. In rectal anesthesia only the necessary ether for narcosis which is excreted by the lungs goes through the respiratory tract, a quantity probably much less than goes through the respiratory passages during inhalation narcosis.

The rapid ether recovery seems to the writer to depend upon two separate factors; first, all the ether in the gut is removed at the time when the anesthetic is discontinued, leaving only that ether which is in the blood circulation to be eliminated. There is no remaining excess as there is in the alveoli. Secondly, the lung has not been impaired in its excretory power as it must be by the tidal flow of concentrated ether vapor in inhalation narcosis.

The fact that *the bowel is inclined to be constipated* may be explained simply by the fact that the bowel has been thoroughly cleaned out before operation and that subsequently the patient has been kept on a light diet. It may be due, however, to over-distention of the gut whereby the smooth muscle fibers of the intestine are made atonic.

The difficulty in producing narcosis in those patients with fecal matter in the rectum is dependent upon two factors. First, absorption cannot take place readily; and secondly, the fecal matter repeatedly plugs the lumen of the tube.

CONSIDERATION OF THE IMPORTANT CASES.

In considering the cases which have been anesthetized by the rectal method, it has been the writer's desire to determine whether or not complications occur more frequently than by inhalation narcosis. An attempt has also been made to learn the experience of men who have employed the method in hopes of determining possible limitations of the method in the hands of those not especially familiar with the technique.

No mention will be made of any case which does not present significant features; and the consideration is here limited to the fatal cases, those presenting complications, and the cases presenting features which illustrate the value of this form of ether administration, in hopes of getting a correct prospective and placing the method in its proper place. I wish to express my thanks to the gentlemen who have helped to make this possible by kindly placing the records of their cases at my disposal.

In my own series of cases, there have been two deaths, one a blind boy six years old, with constitutional tuberculosis and on whom a prolonged operation was performed for extensive tuberculosis adenitis. No criticism could be made of the manner in which the ether was administered and no better narcosis could have been wished. During the latter part of the operation, the patient's condition became bad, the picture being that of surgical shock so commonly seen as a result of a prolonged and severe operation. The patient failed to rally under stimulants and died. It is only fair to state that, had the patient been etherized by inhalation, the operation would have been of even longer duration, and it is believed by those present that the ultimate result would have been the same.

The other fatal case was in a woman sixty-three years old, etherized for Dr. Peer P. Johnson, of Beverly, Mass., who performed an operation for cancer of the neck. The patient was under ether over two hours, and at the completion of the operation was in poor condition. The patient never rallied from the operation and died twenty-four hours later. Previous to death, she had several fecal and gaseous movements. While the first impulse would naturally be to blame the novel method of anesthesia, it will be readily admitted that it is not unusual to have an aged patient die, as did this one, by imposing too great a tax upon an aged individual by a severe and prolonged operation.

Another fatal case occurring after rectal anesthesia was a patient of Dr. J. B. Eagleson, of Seattle, Wash. Being in Seattle at the time, I learned the details of the case. The patient was a child about two years old who was operated upon a second time to perform a succeeding step in the repair of a harelip and a cleft palate. At the first operation, ether was administered by inhalation. Following the operation the child presented symptoms of acetonuria and nearly died. At the second operation, rectal ether was given. The narcosis was satisfactory in every way. The patient made a rapid ether recovery and was normal in every respect for two days following the operation. At this time the patient became drowsy, sank into coma, had convulsions and presented the typical picture of acetonuria, as following the previous operation. The patient died about twenty-four hours later, three days after operation. The nurse was the same one that cared for the child at the previous operation, and she could see no difference in the symptoms subsequent to each operation except that the symptoms came on earlier after the first operation. There were no bloody stools or diarrhea and the patient had been on the floor playing with the other children the day following the operation. While acetone was not sought for in the urine, the quick ether recovery and normal condition existing for forty-eight hours and the chain of symptoms follow-

ing in one who had presented the same symptoms after a previous etherization, leave little doubt as to the real cause of death.

Dr. Freeman Allen, anesthetist to the Massachusetts General Hospital, has kindly placed at my disposal the records of thirteen cases anesthetized by him with this method.

Dr. Allen's first case was a patient with an enormous keloid growth obscuring the mouth as well as the rest of the face, operated upon by Dr. Arthur T. Cabot. Dr. Allen's remarks about this case are as follows: "The patient went under quickly." "Absolutely no inconvenience of any kind during operation." "No diarrhea or intestinal symptoms."

This patient underwent a second more extensive operation by Dr. C. A. Porter. Rectal anesthesia was employed and was highly satisfactory.

Dr. Allen's fourth case is of special importance. This patient was recovering from a lobar pneumonia when there developed a mastoiditis with resulting abscess of the neck. The patient's general condition was poor. At the Boston Eye and Ear Infirmary, the late Dr. Walter Lecompte operating, Dr. Allen administered rectal ether for an hour. Dr. Allen's remarks about the case are as follows: "The patient went under in a very striking manner, the odor being soon perceptible on the breath and being obviously intoxicated by ether in three or four minutes." "He remained in perfect control and in excellent condition during operation." The patient recovered. It is unnecessary to more than allude to the value of administering ether by rectum in cases with pneumonia, or other inflammatory conditions of the lungs.

Dr. Allen's seventh case was a patient sixty-five years of age, operated upon by Dr. G. W. W. Brewster for an extensive carcinomatous growth of the superior maxilla, which plugged the nose. The patient died. Dr. Allen's note is as follows: "Patient made a perfect ether recovery, but died about thirty-six hours later of shock."

Dr. Allen's thirteenth case was an elderly man, weighing 230 lb., who was operated upon by Dr. Samuel J. Mixter, for carcinoma of the lip and submaxillary region. This patient was given anesthol for three minutes and ether by inhalation for five minutes, when the rectal ether was begun and continued for forty minutes, seven ounces being used. The respiration was stertorous and bad throughout, the patient being cyanotic. At the end of operation, the pulse was 100 and of poor quality. There was no vomiting and the patient regained consciousness in about two hours, although the quality of the pulse remained bad. During the following four hours the patient had six or eight blood-colored watery movements, without pain or gas and without clotted blood. Dr. John M. Little, Jr., Dr. Mixter's assistant, cared for the patient until his death, twenty-four hours later. Dr. Little states that the patient's condition was not good at any time after the operation; that there was not enough blood in the stools to cause death, and it is his belief that the patient died of surgical shock.

Of Dr. Allen's cases, there were four not perfectly prepared for rectal anesthesia. One case, however, went satisfactorily, but in the other three, narcosis by inhalation had to be resorted to in order to get the patient under. Two of these unprepared cases had diarrhea. In one the movements were watery; in the other the discharge was bloody, without pain, tenesmus or any discomfort. It lasted three days. Vomiting occurred in five cases. Two cases vomited once only, one twice, another three times, all small amounts; but in another case the vomiting was considerable.

Dr. Frederick Coggeshall performed a trachelorrhaphy and perineorrhaphy followed by a laparotomy for resection of the ovaries, and a Gillian's operation for retroversion in a patient who had suffered severely from vomiting following three previous ether narcoses by inhalation. The frightful vomiting resulting from the previous etherization was the only reason for employing the rectal method. The presence of the rectal tube near the field of operation was objectionable, and when the abdomen was opened, the intestines were distended so that the intra-abdominal operation was made more difficult and inhalation narcosis was then substituted. Dr. Coggeshall's impression of the case is as follows:

"In this case the patient had taken ether several times before with great difficulty and great distress, and had suffered excessively in coming out of it. She was an extremely neurotic woman. Although during the latter part of the operation the rectal etherization was abandoned for the ordinary method on account of the distention of the bowel, most of it, if I remember rightly, was performed under rectal ether. Although this was a much more severe operation than any which she had previously undergone, and although her nervous condition was worse at the time than it had been at any time before, the patient stated afterwards that she was less uncomfortable, both in taking the ether and from its after-effects, than on either of the three previous occasions on which she had been operated upon. She vomited only once instead of doing so steadily for from twenty-four to forty-eight hours as she expected. The bowels moved of their own accord within twelve hours."

A second case performed by Dr. Coggeshall is also worthy of mention because, although the bowels were not properly prepared, the narcosis was satisfactory, and as it also illustrates that one not experienced with the method can employ it satisfactorily. Dr. Coggeshall's impressions regarding this case are as follows:

"The second case was the removal of extensive glands in the neck from a girl of fourteen, in which the ether was administered throughout by rectum, by Dr. David Townsend. The bowel had not been very thoroughly cleaned out before, nevertheless the patient went under without any great difficulty, and the method was highly satisfactory both from the etherizer's and the operator's point of view. The amount of ether used was 100 gm. can of Squibb's, and I think that this was not quite emptied. There was no vomiting afterwards; the bowels moved of their own accord within twelve hours."

"I should go even further, and be very much inclined to try it again, at least, for purposes of getting the patient under the anesthetic in abdominal operations where the patient had had previous experience of great discomfort on going under and coming out of ether administered in the usual way. I might add, as indicating the method is not a difficult one to carry out, that Dr. Townsend had never used it before, and his only practical knowledge of the method was derived from being present on the occasion that you gave it for me; nevertheless, he was able to use it without the least difficulty arising from its novelty to him."

Dr. William C. Peters, of Bangor, Me., states: "I gave ether by rectum to only three cases, all abdominal." "It proved an easy and to the

patient a very satisfactory way to produce anesthesia." "There was no state of excitement." "The patients were a little disturbed at what seemed to them unusual methods, but reported no unpleasant sensations. In no case was it continued after the abdomen was opened on account of distention." "I have intended to try it again, selecting other than abdominal cases."

Dr. J. A. Stucky, of Lexington, Ky.,[8] reported four cases in which he had employed rectal anesthesia and speaks in favorable terms regarding it. In a letter to me Dr. Stucky states, "I find it hard to overcome professional prejudice against the method, but I am so pleased with it I propose to continue it."

In stating the unsatisfactory features where they have existed, it seems important to remark that these unpleasant occurrences are all that have come to light during the use of the method for the past three years.

The method has presented no dangers other than those common to any form of complete narcosis, except in Dr. Allen's fatal case, where the passage of blood by rectum resulted. Dr. Allen feels that the water bath was at a temperature higher than the boiling point of ether, and that ether itself was forced into the gut, to which fact he attributes the bloody stools.

The unfavorable cases cited show that the same dangers are present in administration of ether by rectum as by inhalation, but it is not evident that they occur in any greater frequency. The four cases of shock are consistent with the character of the patients and the nature of the operation; and the cases of acetonuria are no more unusual than the occasional existence of this condition after narcosis by the usual method.

There has been a surprisingly large number of cases in which the narcosis has been satisfactory, even when the bowels have not been prepared. All the cases, however, in which the method has failed have been those in which the bowel was not empty. Although many cases do well without preparation, the method cannot be expected to succeed under these circumstances, and if it is desirable to use rectal ether because of the nature of the case, it should be undertaken with little hope of success. Dr. Lumbar[9] states that the patient should be on a low diet for two or three days previous to operation, but I have not found this necessary. If the bowels can be emptied by the administration of magnesium sulphate the evening before operation and the lower bowel cleansed by a suds enema just before operation, this seems to be all that is necessary. In the recent cases, I have employed a "split" of Abelina water, which seems to empty the bowel satisfactorily without the griping so frequently associated with the use of magnesium sulphate.

I have had the opportunity of observing the amount of intestinal distention in four cases in which rectal ether has been administered. In each instance, the gas had passed the ileo-cecal valve and the small gut was inflated throughout its whole length. Dr. Peters has made the same observation in his cases.

It is possible that the odor of the ether upon the breath may be due to its extension along the gastro-intestinal tract and not to its elimination by the lung.

Dr. N. B. Leggett has employed the rectal method of producing anesthesia in twelve cases, on the services of Drs. Blake and Brewer at the Roosevelt Hospital, New York. The cases have been satisfactory in every way. Dr. Leggett has employed a Y glass tube for joining the efferent and rectal tubes together. By means of a small bit of rubber tubing fitted with a clamp and joined to the other arm of the Y tube, any excess of gas in the rectum may be allowed to escape.

Dr. Leggett has attempted to produce anesthesia with this method in dogs without success, unless anesthesia is first produced by inhalation. Leggett believes that the ether introduced through the rectum does not pass above the ileo-cecal valve, unless this structure has been relaxed by inhalation narcosis. He has given large doses of morphia in hopes of making inhalation narcosis unnecessary, but the results have not been satisfactory. After the dog is once under the influence of ether, rectal ether may continue the narcosis for any length of time. None of Dr. Leggett's dogs have died nor have they had any rectal disturbances.

The cases cited in which the method has been of special service speak for themselves.

At an exhibition of the method before the Clinical Surgical Society at the Boston City Hospital in 1905, the impression received was entirely bad, it being impossible to get the patient under. It was subsequently learned that the ether bottle contained a little ether and a large amount of salt solution. This practical joke, if it may be so called, justly influenced those present against the method. Some of these gentlemen have since seen the method demonstrated under more favorable circumstances.

THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS FOR THE GENERAL PRACTITIONER.*

BY EDWARD O. OTIS, M.D., BOSTON,

Consulting Physician to the Massachusetts State Sanatorium; Physician to the Lung Department of the Boston Dispensary.

In the strict sense of the term an early diagnosis of pulmonary tuberculosis cannot be made, for the evidence does not permit of it. It is a fact of not uncommon observation that in autopsies of persons dying of some other disease, an old tuberculous cicatrix is found in the lungs, which had manifested no symptoms or produced no impairment of the ordinary health during life.

What we understand, however, by an early diagnosis is the earliest possible moment that we can detect the disease, either by physical signs or

* Read before the Ninth Annual School of Instruction for Health Officers of Vermont, at Burlington, June 19, 1907.)

constitutional symptoms, or both, or by bacteriological proof; and in order to do this, the tubercular process must have reached a certain minimum amount of involvement of tissue and produced a certain amount of change sufficient to interfere with normal resonance and respiration, or to produce an impairment of the general system indicated by the presence of various constitutional symptoms.

We have in the past been inclined to say that if our physical and bacteriological examination was negative, pulmonary tuberculosis did not exist, or, at least, that the evidence of it was not at hand, even if the general symptoms plainly indicate its existence, or made it highly probable that the disease was present.

We may regard an early diagnosis of the disease from two points of view. First, that dependent upon physical findings, which is rarely if ever a genuine early diagnosis; and, second, that dependent upon general symptoms and history, or determined by the tuberculin reaction, which more nearly approximates a genuine early diagnosis. Indeed, by the term "early diagnosis," we now mean that stage of the disease when the evidence is almost entirely from constitutional rather than local symptoms, when the examination of the sputum, if any exists, is so often negative, and when the physical signs are lacking or uncertain.

It is this latter early diagnosis which, I believe, the general practitioner should seek to make, and in which, in my opinion, he will be the more successful; for even if a few physical signs exist in the lungs, they are difficult of detection and not always easy of interpretation even to the most accustomed ear.

First of all, we will consider the early diagnosis of pulmonary tuberculosis from the standpoint of the early symptoms as the most important consideration of the subject, and see how nearly we can arrive at an approximate or probable diagnosis from such symptoms; and, secondly, some of the earliest physical signs discoverable will be considered.

Norris says[1] that "there are four easily ascertained and highly suggestive symptoms, the existence of which should always arouse our suspicion unless their presence can be definitely explained upon other grounds. They are (1) rapid pulse; (2) evening rise of temperature; (3) loss of weight; (4) cough." "The protracted existence of any two of these symptoms," he continues, "requires that good cause be shown why diagnosis of tuberculosis should not be made."

Cough, no matter from what alleged cause, if it is continued for six, eight or ten weeks, should always excite suspicion and demand careful investigation. Of course, we may have a lingering bronchial cough, particularly that resulting from an attack of influenza, but the burden of proof rests upon us that such a cough represents nothing more than the bronchitis.

It is an all too common experience that a patient comes to us with more or less advanced tuberculosis who has been told that the cough which has continued over many months was the result of bronchitis, and hence he was deluded by the false hope that it would disappear in time, and was not of serious import. Much less harm would result, in my opinion, if every cough of over eight or ten weeks' standing should be regarded as indicating tuberculosis and the patient treated for the disease if no other discoverable cause for the existence of the cough should be found.

A probable diagnosis of tuberculosis should be made, says Wilson, in a case in which a long persistent and otherwise unexplained cough is accompanied by either a sub-normal temperature or one that rises slightly during the afternoon.

We are all familiar with the short, hacking, hardly noticeable cough of tuberculosis. It is sometimes hardly more than a clearing of the throat, and even its existence may not be recognized by the patient unless a thorough investigation is made. Such cough is of very little consequence in the patient's estimation: it causes him little or no annoyance, and, in fact, may only occur in the morning. In proportion, however, as it is slight, but continuous over a long period of time, particularly if it occurs only in the morning and is accompanied with some expectoration, however slight it may be, it is to be regarded as evidence of probable tuberculosis, unless other evidence disproves it.

A rapid pulse, particularly when apparently of diminished tension, is another highly suggestive symptom of pulmonary tuberculosis, and should lead to the careful scrutiny of other symptoms. Brehmer, who first established the present universally accepted open-air method of treatment, and who was a keen observer, maintained that in tuberculous individuals the heart was disproportionately small to the size of the lungs, and others have held the same view. However one may regard this theory, it is a fact of common observation that a rapid and more or less weakened heart is not an uncommon symptom in early tuberculosis, and therefore should always lead to further inquiry in a suspected case. Dunham[2] considers the best symptomatic guide to be the condition of the pulse taken in the latter part of the day, and if, while resting, the pulse is found to be constantly 90° F., the probability of tuberculosis should be strongly suspected; and, further, if at the same time there is a slight rise of temperature, even of a few tenths of a degree, frequently occurring, these two symptoms, viz., rapid pulse and slight increase of temperature, should be sufficient to establish the diagnosis of tuberculosis, other causes being excluded.

An increase in temperature, even if slight, if it is persistent, is, as we know, a leading symptom unless otherwise accounted for, and when accompanied by other corroborative signs would lead us to make a highly probable diagnosis of pulmonary tuberculosis. One should, therefore, in any suspected case, take the temperature several times a day for a week, and this can be done

[1] "The Diagnosis of Incipient Pulmonary Tuberculosis," reprint from American Medicine, June, 1906.

[2] Personal communication.

either by the patient himself after a little instruction, or the patient can present himself at the doctor's office daily for the purpose.

Loss of weight, if more transitory, indicates that some chronic affection is disturbing metabolism and assimilation, and if accounted for by no other satisfactory cause is highly suggestive of tuberculosis, since this disease is so prevalent that it is more likely to produce this condition than any other.

In like manner is loss of strength, even if slight, an important danger signal pointing towards the direction of tuberculosis.

Again, a slight amount of breathlessness on exertion, like mounting stairs or a hill, is highly suggestive. When one becomes easily fatigued from insufficient cause, and when this is associated with even slight dyspnea on exertion, in the absence of cardiac lesions, it is strong evidence of probable tuberculosis.

Digestive disturbance and more or less anorexia are indications of an infection of some kind, and if other indications point towards tuberculosis, it is probable that the bacillary infection is causing this disturbance of metabolism and assimilation. Pryor, however, says that loss of appetite and indigestion are not noticeable to any great extent as a rule during the early manifestations of the disease. The entire attention of the patient may be directed to the digestive disturbances, and the tell-tale symptoms of loss of weight and strength, and the cough, may all be referred to a disturbed condition of the stomach, a natural mistake on the part of the patient, and an occasional and unfortunate one on the part of the physician.

Although, as we now know, pulmonary tuberculosis is not inherited, a lessened resistance to it, or at least a susceptibility, to it, is apparently a matter of inheritance, and therefore the family history is of importance; and when such history is positive it should render us very suspicious of all symptoms, however slight.

Hemoptysis is almost pathognomonic of pulmonary tuberculosis unless we can clearly prove that the hemorrhage is the result of mitral stenosis or from some other definite source; we can make it a rule, which has few exceptions, to regard such cases of hemoptysis as tuberculous.

"The three most important symptoms," says Pryor, "which may reliably guide us, are hemoptysis, fever and loss of weight when they cannot be otherwise explained." Indeed, it is fortunate if the first symptom that comes to our attention is hemoptysis, for then we have the diagnosis at once established and treatment can at once be instituted.

From considerable experience and observation, I am of the conviction that the majority of cases of pleurisy are of tuberculous origin, and hence in any case of pleurisy, particularly when accompanied with serous effusion, one must bear in mind a possible and probable pre-existing tubercular infection, and observe with great care the subsequent course of the pleurisy.

There are other symptoms of more or less importance which all have corroborative value in connection with those already mentioned. Such are dilatation of the subcutaneous vessels indicated by a prominent veinous network, the result probably of a vaso-motor disturbance due to the tubercular infection; a tendency to ready perspiration, even in cold weather; chilliness; paleness; more or less anemia; looseness of the bowels in some cases, or, more often, constipation; hoarseness and others.

One should also carefully inquire into the habits, the occupation, possible exposure to the disease, and the previous illnesses of the patient, and (which is important) give the patient an opportunity to tell his own story in his own way.

In many cases, the majority, Dunham thinks, the patient will declare that he has always been well, with the exception of some of the specific infectious diseases of childhood. And if the disease is well established or moderately advanced the patient will give a history of several attacks of "influenza," or having suffered from what was supposed to be "malaria." Sometimes, also, he will refer to typhoid fever as having occurred sometime previously. Not improbably, these were manifestations of active tubercular infection mistaken for these diseases.

Secondly, what are the earliest physical signs? I would repeat that, in the early diagnosis which we have been discussing, as a rule, there is no marked evidence of disease in the lungs. As Janeway says, there may be an absence of physical signs and yet a presence of the disease.

We may consider physical examination under three heads: inspection, percussion and auscultation. Of these three, *auscultation* renders the most valuable service and perhaps is generally the only means of determining any abnormal physical condition in the lungs, in early cases. In inspection (and the patient should always be stripped to the waist for a proper examination, whether man or woman), one observes the condition of the skin, subcutaneous veins, shape of the chest, evidence of loss of flesh, glandular enlargement, and readiness to perspire. In watching the patient's breathing, it is not infrequently noted that there is a retardation of the respiratory movement over the affected lung.

As a rule, in the very early stage when any physical signs are present, one learns nothing or but little from percussion, for at such a time percussion is practically normal, or there is so little deviation from the normal that it requires the most acute and highly trained ear to detect it.

It is upon auscultation that we must depend practically for the detection of changes in the lung tissue due to tuberculosis, and we may consider it almost an axiom that *anything* abnormal heard in the apices of the lungs is to be regarded as the strongest kind of evidence, almost amounting to proof, that tuberculosis exists. Such changes are revealed through auscultation, first, by the respiration; second, by the presence of adventitious sounds. The most important respiratory change is what the Germans call "rough

breathing," and weak or slightly diminished breathing.

Next in importance, according to the National Association, is the presence of râles, which I would consider of the first importance, as they are the most constant and the most easily determined sign. Slight dullness and slight changes of respiration are uncertain of detection, and even the most skilled diagnosticians are often in doubt as to their real existence. Hence the difficulty of drawing any positive conclusions from these sounds. But localized râles are certain and, when found, prove almost conclusively the existence of pulmonary tuberculosis. It does not matter so much what name we give these râles or their exact character. In general, they are fine crackling râles, but we can call them clicks, crepitations, fine, moist râles, crepitant or subcrepitant râles, or whatever we please, if we only recognize them. They are generally found above the clavicle, or below it in the middle or outer third, or behind in the suprascapular fossa. They are heard most frequently after a single slight or genuine cough followed by a deep inspiration.

Turban mentions the incident of a patient who had been through many doctors' hands, and who decided the diagnostic ability of his adviser by whether or not he asked him to cough during examination.

I do not mean to say that changes in the respiratory murmur which I have mentioned, namely, the harsh breathing, weak or diminished, breathing, etc., are not of important diagnostic value when they can be surely made out, but one must confess that to most examiners their existence is often in doubt, and, consequently, they are uncertain symptoms.

"The great and predominant value of the localized râles," as Whitney[3] says, "in the diagnosis of incipient tuberculosis consists, first, in their almost constant presence at a time when other local signs are absent, or at most indefinite; second, in their practically unmistakable character, themselves differing widely from other signs which represent merely deviations from the normal; third, in the fact that when occurring at the apex they are almost pathognomonic, other conditions which might produce them being exceedingly rare."

While, therefore, other local signs are of great value, especially for the few experts who by long experience have learned their limitations and the frequent difficulty of interpretation, the presence of localized râles must ever remain the essential guide to early diagnosis from physical signs for the rank and file of the profession.

"The earliest physical sign," says Hector MacKenzie,[4] "which is really characteristic, is the presence of râles or crepitations."

Dr. Henry I. Bowditch, the elder Bowditch in "The Young Stethoscopist" 1848, many years ago pointed out a sign which I have not infrequently verified and which I believe of much value in early diagnosis. "Not infrequently," he says, "a sound like a simple whistle or sonorous râle is heard above the clavicle, while in the remainder of the chest there is a healthy vesicular murmur. This strongly indicates the existtence of tubercular disease of the patient, if the patient is suffering from a chronic affection, especially if it be connected with any other morbid physical or rational sign."

As the disease advances, other plain and evident physical signs appear, the consideration of which does not come within the scope of this paper, and which are all familiar to you.

One other valuable aid to the early diagnosis I cannot, however, pass by, namely, the use of tuberculin. I have used it in a very considerable number of cases, and have never known it to produce any injurious results. I believe, with ordinary care, it is harmless, and will frequently enable us to establish beyond a doubt the existence of the disease. The technique of the procedure is simple and plain and within the skill of any practitioner. The dose, I believe, should be small, at least to begin with, from $\frac{1}{10}$ to $\frac{1}{2}$ mgm.; and if reaction does not occur, then 2 to 5 and even 10 mgm. should be used at intervals. I used Koch's old tuberculin, which can be very readily diluted so that the fractions of the milligram can be easily measured.

I will not take the time to consider the various signs and symptoms which constitute a reaction, for such are readily accessible in the abundant literature upon tuberculosis. I believe, however, that any practitioner who makes a trial of this test will be convinced of its value and harmlessness.

In the preceding I have merely discussed some of the points which, I believe, are of the most importance in making an early diagnosis. Many other secondary signs and symptoms have of necessity been omitted, but if one will confine himself to those which have been mentioned and become thoroughly familiar in their detection, I am sure that he will rarely fail to make either a definite or probable early diagnosis; and, as we know, if a direct diagnosis is made in the early stages, we can almost certainly bring about complete arrest of the tubercular process. And, as Knight says, we should not wait in all cases for a positive diagnosis before putting our patient with suspicious symptoms under the best possible conditions for recovery.

In all cases it is, of course, understood that the sputum, whenever it exists, should be examined for the tubercle bacillus; but in the majority of early cases, this evidence will not be obtained, and it cannot be too often repeated that to wait for the presence of the tubercle bacillus will in many cases mean, to wait until the disease is moderately or far advanced.

The following cases will illustrate my thesis, and were kindly selected for me by my colleague at the Massachusetts State Sanatorium, Dr. Dunham:

I. *5178 B.* Male, thirty-two, single, bricklayer. Slight cough and expectoration over two months. Lost twenty pounds in two years; rather "bilious"

[3] "The Predominant Value of Localized Râles as a Sign of Incipient Phthisis," reprint, May 18, 1905.
[4] Gibson's "Text-Book of Medicine."

lately. Pulse 100 in the evenings and temperature 99–2°–4° at the same time. Tubercle bacilli not found in the sputum on three examinations (but found later). Small area of faint bronchial respiration in the left lung, just above and outside of the border of the heart. A *few scattered* râles in the upper part of the left lung.

II. *5036 B.* Male, nineteen, cigarmaker. Coughed three or four times a day for a month. Little or no expectoration. No bacilli. Temperature and pulse fairly good, but since found to be rather high. Loss of six pounds in weight during the month. Physical signs negative. Patient raised half a cup of blood three weeks ago, the only factor for making positive diagnosis.

III. *5084 B.* Male, married, forty years old, street car conductor. Had a little cough during the winter at times; raised very little at times. No loss in weight; general condition excellent. Slight shortness of breath on much exertion. Physical signs: the very faintest clicks heard above both clavicles. Temperature and pulse normal. Patient still at work. Tubercle bacilli found in trace of expectoration raised on that morning (morning of examination) and were found twice later. The only thing which brought the patient for an examination was a little streak of blood which he saw in what he always regarded as throat catarrh.

IV. *5124 B.* Widower, age forty-five, mason. Slight cough for six months. Little sputum. Lost ten pounds in weight; pulse and temperature normal, Very little to find in his chest on physical examination. Percussion note on both tops seems to be poor, and one or two slight clicks are heard in the left back. However, many tubercle bacilli were found repeatedly upon microscopic examination.

V. *4774 B.* Male, single, age twenty-five, priest. Very slight cough and expectoration. Considerable dyspnea on much exercise. Lost twelve pounds in three months. Pulse and temperature normal. Examination of the sputum by Board of Health negative. He had bronchitis three years ago and pleurisy seven or eight years ago. This might be looked upon as a case of bronchitis if it were not for the fact that there were dullness, râles and br. v. resp. in the right apex, front and back, and many tubercle bacilli constantly found in the expectoration (after the first negative report mentioned).

VI. *5070 B.* Male, single, age twenty-three, mechanic. Practically no cough or sputum. Physical signs very marked, however, in the right top, and pulse decidedly rapid, although there had been no loss of weight. Tubercle bacilli abundant in the trace of expectoration he was coaxed to give.

VII. *5214 B.* Male, single, student; pneumonia eight years ago. Little cough for three or four weeks. Raised a trifle only during the past two days. Eight pounds below normal weight. Difficult to find anything in the lungs except a *few* clicks in the left supraclavicular region; pulse, however, is 100 and a few tubercle bacilli have been found in his sputum.

VIII. *5012 B.* Male, single, nineteen, clerk. Slight cough for seven months. Loss of twenty pounds in the last three months. Almost nothing abnormal heard in the lungs, chest broad and well shaped, respiration good. History of spitting teaspoonful or two of blood on one occasion. Twelve examinations of the sputum negative after one positive. Tuberculin reaction positive.

MEDICAL FEES IN GERMANY. — The High Court of Germany has decided that it is illegal for the physicians of any locality to band together and establish a definite code of fees for professional services. — *Medical Record.*

REPORT ON A PECULIAR DISEASE OF TROPICAL AFRICA CALLED "ONYALAI." *

BY F. CREIGHTON WELLMAN, M.D., BENGUELLA, WEST AFRICA.

DURING the three or four years that have elapsed since the writer first reported the existence of the disease called by the Umbundu-speaking natives of Angola "Onyalai," several workers have written concerning the same or a similar affection, and a *résumé* of these observations may be helpful. Since my first note I have studied several additional cases with the object of determining the cause of the various symptoms, and the data relating to these are here presented for the first time.

HISTORICAL NOTE.

1. The first mention of the disease was, I believe, my initial note published early in 1904. In this I stated that hemorrhagic bullæ are a feature of the trouble and added the following: [1] "Onyalai" is "a common and very treacherous disease, greatly feared by the natives, considered by them very fatal. I was once disposed to treat the native view very lightly, but after seeing cases die from it in a few hours from the beginning of an attack, I revised my notion. The bullæ may be small and affect only the surface of the body, or occur only on the tongue, soft palate or buccal mucous membrane. When large and involving the esophagus and pharynx they may cause trouble, but when they occur in the brain, its membranes, or even in the important abdominal viscera, death often results. The size of the bullæ varies markedly, ranging from that of a split pea to that of a half crown piece." Later [2] I repeated this note and added that "the disease is not pemphigus, *Dermatitis herpetiformis*, nor the affection known as *Epidermolysis bullosa*. The bullæ appear suddenly after an initial period of malaise. . . . The vesiculation is rather deep and, when occurring in the skin, always involves the corium. The bullous formations contain trabeculæ, the interstices of which are filled with partially coagulated blood, to which their dark colour is due. The disease generally disappears (if death does not occur) as suddenly as it came."

2. Massey [3] published, subsequent to my preliminary note, the record of three cases of "Onyalai" seen by him in Angola. These cases all had symptoms similar to those detailed by me and all recovered. Massey states (what coincides with my experience) that the blacks are very much afraid of the disease, regarding it as most fatal. He treated his cases with bicarbonate of soda and cod liver oil.

3. Feldman [4] has mentioned a disease among the natives of Bukoba in East Africa and called by them "Edjuo" which Mense [5] is inclined to connect with "Onyalai." Feldman noticed stomatitis and swelling of the parotid glands in connection with his cases.

4. Mense [6] observed during his stay on the Kongo a disease, called by the Unyamwezi people "Kafindo" which spread across equatorial Africa

* Published under the imprimatur of the American Society of Tropical Medicine. Received for publication July 19, 1907.

and which was marked by depression, malaise, headache, reddened conjunctivæ, numbness, swelling of the tongue, loss of appetite, and occasional bloody diarrhea, dyspnea, cardiac disturbances, etc., all of which symptoms I have seen in my cases of "Onyalai." Mense states, however, that the peculiar bullæ described by me were not noticed in his cases. He did not personally observe any cases that terminated fatally, but such were reported from East Africa. He differentiates "Kafindo" from dengue and other diseases and discusses its possible connection with poisoning with Euphorbiaceæ and other native plants. Mense in conclusion mentions the native treatment, which consists of scratching the tongue until bleeding occurs, and that of the missionaries (phosphorus, essence of bee venom) and recommends for the stomatitis astringent mouth washes.

It is not absolutely certain that these several observations all relate to the same disease, but it is very probable that they deal with identical or closely related affections. I know of no other literature on the subject.*

ETIOLOGY.

Obscure. Following are notes on some of the investigations I have made regarding this point. The results of my inquiry are largely negative and may be stated as follows:

1. "Onyalai" is not a manifestation of malaria. While the hemorrhagic and other symptoms of the affection under discussion are not unknown in malarial processes, yet I consider that I have excluded this infection as an etiologic factor. I base this statement on the following data: None of my first 8 cases had any enlargement of the spleen and but three of them showed rise of temperature. These 3 were examined for malarial parasites but none was found. None of my 5 recent cases showed enlargement of the spleen. Only one of them showed malarial parasites in the blood. In another case I found some pigmented leukocytes. This case, however, had just come from a very malarious district and I had administered to him large doses of quinine for some days. None of the other cases had had quinine. Twelve of the 13 cases were suddenly taken ill while in robust health. Also 12 out of my 13 cases were males. Two of Massey's cases were males. The sex of the third is not given. Nearly half of the cases had experienced the same trouble before. In two instances two members of a family were affected and in four instances more than one case came from the same house. All these facts suggest to my mind something very different from malarial infection which is almost universal among Africans while "Onyalai" is comparatively rare. While preparing my recent report to the *Società per gli Studi della Malaria*,[7] I examined microscopically the blood of over 500 natives and took the spleen index of as many more, and I find on comparison that my cases of "Onyalai" were rather freer from the signs of malaria than the average native of my district.

2. "Onyalai" is not accidental or purposed poisoning. I have had occasion to study the various substances included in the poison test [8] and those formerly used to poison arrows [9] as well as the medicinal plants employed by the blacks of this district [10] and the symptoms set up by poisoning with any of these are radically different from the clinical picture presented by a case of "Onyalai." A case of snake bite from the puff adder (*Clotho arietans*, Gray) which I reported some time ago [11] simulated some cases of "Onyalai" very closely, but my patients had none of them been bitten by snakes.

3. Trypanosomes and other organisms were searched for with no result. On two occasions I cauterized the surface of large bullæ and cut down on the inclosing clot, removing a piece of the same and dropping it into sterile broth. Such cultures remained sterile.

4. "Onyalai" is easily and sharply distinguished from Schönlein's disease by the absence of the multiple arthritis, eruption, etc., and from Henoch's purpura by its frequency in adults and acute course. It cannot be identified with *Purpura hemorrhagica* as it occurs oftenest in robust and adult males. It must be emphasized, too, that the superficial hemorrhagic bullæ are by no means to be considered the only nor indeed the chief factor in the disease, for, as will be shown later, I have seen two fatal cases of what I believe to be this ailment in whom no bullæ were visible, either on the skin or mucous membranes. In other cases they were so small and few in number as to be easily overlooked. There do not occur to me any other diseases for which "Onyalai" is likely to be mistaken.

To sum up: I am inclined to consider "Onyalai" a specific entity, in other words an acute infectious disease the cause of which is as yet undetermined.

CLINICAL FEATURES.

Most of my cases were attacked suddenly. Lassitude and a sort of dazed appearance was generally marked. In some cases the parotid glands were tender to the touch. The eyes appeared heavy and sometimes reddened. In most instances the tongue was swollen and painful. A slight temperature was noted in about a third of the cases. I have had patients complain of numbness and of pain in various parts of the body. One man who had bloody diarrhea suffered much from colicky pains. The appetite is usually poor. The bullæ may appear in the mouth, pharynx, esophagus, stomach and bowels. Vomiting of blood is not rare. The skin also usually shows lesions. The genito-urinary system was affected in 3 of my cases. Hematuria was a prominent symptom in all of these. When the process occurs in the cranial cavity various symptoms of profound central disturbance are

* Maxwell (*Journal of Tropical Medicine*, July 1, 1901, p. 211) has reported hemorrhagic bullæ of the mouth and pharynx seen by him in Changpo, South China. These, however, probably have no connection with "Onyalai" since, according to Maxwell, the bullæ are confined to the oral cavity and are accompanied by no systemic symptoms. The Chinese attribute the bullæ to the accidental introduction into the mouth of a certain kind of spider web.

set up. Three cases of this kind have come to my attention. One of these was a young woman in rude health. She was laughing and playing on the evening of her attack. Suddenly she complained of being tired, and in an hour or so bullæ appeared in her mouth. She steadily grew more depressed and died about eight o'clock the next morning with all the symptoms of cerebral hemorrhage, *i. e.*, loss of consciousness, inactive, dilated pupils, slow, noisy, stertorous breathing, etc. The pulse was very slow and increased in tension. Another fatal case in the same house, a strong young man being the victim, presented almost exactly the same symptoms. A third fatal case showed no vesicles, either in the mouth or in the skin. The feces and urine likewise contained no blood. Another case which I have also referred to this disease also showed no vesicles, but died from the effect of what I believe to be the same process in the liver, spleen and pancreas. (These last two cases were shown microscopically not to be pernicious malaria.) The superficial bullæ when present are characteristic. They range from the size of a split pea to several inches in diameter. The larger ones are irregular in outline and are often umbilicated. They are deep and involve the corium or submucous structure. There seems to take place an extensive histolysis, only the fibrous elements persisting. These appear as trabeculæ, the interstices of which are filled with partially coagulated and otherwise altered blood which shows dark under the skin or mucous membrane. The red corpuscles, however, are not all disintegrated, and may be seen under the microscope in the oozing from the blebs and also in the feces, urine, saliva, etc., according to the situation of the lesions. In one or two cases the bullæ were very small and not numerous, and had the patients not directed attention to them would probably have been overlooked.

PROGNOSIS AND TREATMENT.

My series of cases is yet too small to admit of general statements. As has been said, the natives consider "Onyalai" to be a very fatal disease and tell of instance after instance that have terminated in death. Of the 13 well authenticated cases studied by me 2 died. To these should probably be added the 2 cases previously mentioned which showed all the symptoms of the disease excepting the characteristic bullæ. The malignancy of the disease varies greatly, judging from native reports, some seasons and districts exhibiting many more fatal cases than others. It should be said that the trouble has a tendency to recur. I have seen one man who has suffered three attacks and another who has had two. The relapses seem to occur a few months apart.

As to treatment I am not prepared to be dogmatic. The natives employ various plants, prominent among which is *Geigera wellmani Hutch*, and a species of Albizzia (*A. anthelmintica* A. Brong.). I have personally tried quinine, various alkaline salts, oil of turpentine, acetate of lead, tannic acid, ergot and suprarenal extract with no perceptible results. I am inclined to think that arsenic in full doses has benefited some cases.

In conclusion I should be pleased to hear from any colleague who has met with the disease.

Reports of Societies.

TRANSACTIONS OF THE TWENTY-NINTH ANNUAL CONGRESS OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

HELD AT WASHINGTON, D. C., MAY 7, 8 AND 9, 1907, IN CONNECTION WITH THE SEVENTH TRIENNIAL CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FIRST DAY, TUESDAY, MAY 7.
SESSION AT 10 A.M.

PRESIDENT'S address by DR. A. W. DE ROALDES, New Orleans, La.

The President thanked the Association for the honor it had conferred upon him and alluded to his own work in the establishment of the Hospital for Eye, Ear, Nose and Throat Diseases in his own city. He felt that it was the Association's duty to push the work of securing for the specialty a greater recognition than it yet enjoyed in the medical schools, and that a further need of the times was the establishment of more special hospitals for this class of diseases. This would not at all interfere with special departments in general institutions. He also announced his intention to establish a prize fund for the Association. This suggestion had been made many years ago by the Association's first president, the late Dr. Louis Elsberg. He referred to the deaths of Senor Manuel Garcia, Honorary Fellow, and of Dr. William Carr Glasgow, Active Fellow, both of whom died since the last meeting. He also referred to the celebration of Professor von Schroetter's seventieth birthday in Vienna, to the similar celebration in honor of Prof. Bernhard Fraenkel, in Berlin, the pleasure felt in welcoming Prof. Gustav Killian, of Freiburg, to the present Congress and the proposed Tuerck-Czermak Congress to be held next spring in Vienna to celebrate the semi-centennial of the establishment of systematic teaching in laryngology.

TUBERCULOSIS OF THE ACCESSORY SINUSES OF THE NOSE.

The scientific business of the congress was opened with a paper with the above title, read by DR. J. W. GLEITSMANN, of New York City. The paper, which closed with a bibliography of recorded cases, was in the main an analysis of these cases. The majority of instances of sinus tuberculosis are referable to extension from some adjoining focus. In 20 antral cases, tuberculosis of the bones of the nose or the upper maxilla was found 12 times. The majority had pulmonary disease, and only a few had the local disturbances of antral disease without constitutional symptoms, but

at operation tubercle bacilli were found in the antral contents. In 8 the bacilli were found in the external discharge. Tubercle of other sinuses must be rare, as the author has found records of only 4 cases of frontal disease and one of combined ethmoidal and sphenoidal disease. Pathological changes are very much the same as in nasal tubercle. Empyema, exuberant granulations, caries, cheesy deposits, — all are found, while examination of the sinus lining has shown exfoliation of epithelium, extensive small-celled infiltration, penetrating the superficial as well as the deep layers of the mucosa, while the middle strata have revealed the fibrous structure of the connective tissue containing serous liquid and some leucocytes. Efferent glandular ducts and their lumina have been enlarged, giving rise to cystic spaces, and giant-cells have been found in the infiltrated tissue. Of the entire number only 3 cases showed confinement of the tuberculous process to the antrum, viz., the cases of Coakley, Gaudier and Keckwick. Dr. Gleitsmann gave summarized clinical histories of some of the more important cases. Prognosis must be regarded as unfavorable. Treatment is eminently surgical and does not differ from that generally adopted in severe cases of sinus disease. It naturally has to be more radical as not alone the soft parts but all diseased bone has to be removed. General health must be supported, drain on the system combated and the patient's mental condition encouraged. We have no positive knowledge up to the present time that tuberculin or any of its derivatives would make any impression on these sinus cases. Not much could naturally be expected from such remedies under the given conditions or from the opsonin plan, for all these are principally confined to the elimination of bacilli (found in only a minority of sinus cases) and they do not influence directly the conditions due to the extension of the pathological process. Dr. Gleitsmann finds no contra-indication, however, to their use and would be inclined to try them in view of the favorable results reached in uncomplicated nasal tuberculosis.

DR. C. G. COAKLEY, New York, gave some additional facts as to his own patient whose case was referred to by Dr. Gleitsmann. This patient had been under observation for over two and a half years, and when last seen had no evidence of the disease in any other part of the body. Diagnosis was positive in this case as giant-cells containing tubercle bacilli had been found in the tissue removed from the antrum.

PROF. GUSTAV KILIAN, of Freiburg, a guest of the Association, stated that he had had a case of multiple tuberculosis of the bones with caries of the left frontal sinus. Operation was followed by recurrence of the sinus condition. There was tuberculosis of the maxillary bone and of part of the antral walls but no pus. Tubercles were found in the mucosa of the frontal sinus.

DR. HARRIS P. MOSHER, Boston, referred to a low grade of tuberculosis, a scleritis which has defied treatment and diagnosis as to cause. Finally, the use of tuberculin determined its nature. Dr. Mosher had recently been giving tuberculin in certain sinus cases but thus far had obtained no reaction. In the ordinary forms of tuberculosis in sinuses it was difficult to find bacilli. He would not consider tuberculin as of much value in these cases as compared with the usual methods of surgical intervention. The discussion was closed by Dr. Gleitsmann who referred to the work of Bartles who had endeavored to formulate the condition known as the tubercular state, declaring that before this period arrived there was a pre-tubercular epoch manifesting itself mainly in lymphoid infiltration, a hydremia of the parts involving the lymphoid tissue similar to the hydremia observed in septic cases before real septic symptoms manifested themselves.

MASSAGE OF THE PHARYNX.

A short paper on this topic was presented by DR. SAMUEL W. LANGMAID, of Boston, who exhibited an instrument which had been devised for the purpose named, by an eminent tragedian, the late Edwin Forrest. This instrument was a smooth wooden handle with curved ends which Forrest was accustomed to sweep around in his throat in order to "ream out the old trumpet," as he expressed it. It had been impossible for various reasons to discuss with the actor the latter's views as to the value of the manipulations referred to. Dr. Langmaid had long been accustomed to recommend to his patients massage of the throat by some such implement as the broad, rounded extremity of a tooth-brush handle. It greatly reduced the irritability of the pharynx, removed enlarged follicles on the posterior wall and in general seemed to reduce hyperemia. Since writing his paper he had found that a century ago a certain British admiral, who wrote more as an osteopathist than as a masseur, recommended instrumental massage of the mouth and throat, not only as a prophylactic measure but as curative also for sore throat.

DR. J. SOLIS-COHEN, of Philadelphia, stated that he had often used the so-called extension-finger of the dentists in pharyngeal manipulation so as to accustom patients to the handling of the epiglottis.

DR. G. HUDSON-MAKUEN, Philadelphia, believed that in these cases much could be done in showing the patient how to keep quiet during examinations by having him manipulate the pharynx with the handle of a tooth-brush or similar instrument. The patient's attitude is too often one of self-protection rather than of co-operation, and he should be taught to give the physician intelligent assistance. Dr. Makuen could not agree with Dr. Langmaid's statement that singers and speakers have anemic pharynges.

DR. CLARENCE C. RICE, New York, was inclined to agree on this point with Dr. Langmaid. In his experience noted singers and actors did not, as a rule, have much chronic pathological change in their throats. His own feeling was that the strong use of the voice and vibratory massage of the pharynx tended to atrophy and anemia rather than to congestion. If he found congestion in a singer's pharynx without any special nasal or post-nasal catarrh, he would ascribe it to tobacco or alcohol rather than voice use. In general, intelligent massage was a useful therapeutic measure

Discussion was closed by DR. LANGMAID who wished to emphasize the value of instrumental massage of the throat. Vessels were thereby reduced to their proper size by the flowing away of the excessive blood, and there ensued a tonic contraction of the tissues.

BILATERAL ABDUCTOR PARALYSIS OF THE LARYNX.

A case of this nature was reported by DR. CHARLES H. KNIGHT, of New York City, who notes that the lesion referred to is more common than authorities have led us to believe. It is often difficult to distinguish between abductor paralysis, adductor spasm and ankylosis of the crico-arytenoid articulation, and prolonged observation is often required in determining the actual condition in a given case. The author passed in review the differential features diagnostic in the conditions named and then reported the case of a middle-aged man of nervous temperament who in childhood had had chorea and had been subjected to severe nervous strain. Had been alcoholic for one year, some years before coming under notice. Six years ago had an attack of ptomaine poisoning. For the year following suffered increasingly from rapid heart action, dyspnea

and vertigo. Later developed sciatica presumed to be the forerunner of tabes. Six years ago contracted syphilis and had the usual secondary symptoms but received thorough treatment. One year ago he was suddenly awakened one night struggling for breath. Later when running for a train he had his first attack of laryngeal spasm. During the last six months he has had some 12 or 14 repetitions of this spasm, all but one or two coming on during sleep. Sometimes the attacks have followed excitement or exertion. After exercise there is always inspiratory stridor. The laryngeal image was typical of bilateral paralysis of the abductors, with a moderate grade of catarrhal inflammation. A redundant uvula was excised, inhalations of metholized oil given, with strychnine and iodide of potash. Electricity seemed to aggravate the patient's symptoms. Under the foregoing régime there has been some improvement. The author referred to the following proposed measures in such cases: (1) intubation, (2) ablation of the soft parts lining the voice box, (3) division or resection of the inferior laryngeal nerve and (4) tracheotomy. His personal experience had been limited to the first and last. In this particular case one observer who had previously seen the patient urged immediate tracheotomy, but this was refused by the patient, who preferred death to wearing a tube. Dr. Knight thought that up to the present time at least the result seemed to have justified this decision. He considered that in such cases the ideal procedure, on theoretical grounds at least, was resection of one recurrent nerve whereby the corresponding vocal band would be placed in the cadaveric position and the voice would finally be regained through compensating action of the adductors of the opposite side. He had been unable, however, to find any successful record of such a case. Mere division of the nerve is useless, as it is possible that in some of these cases a portion of the innervation on the adductors is derived from the nerve of the opposite side and, in addition there may be more or less ankylosis of the crico-arytenoid joint. Tracheotomy will doubtless afford us the most satisfaction. It is best done under local anesthesia. The onset of dyspnea is often alarmingly sudden. Prognosis in such cases is less hopeless than is generally believed.

REMOVAL OF PAPILLOMATA OF THE LARYNX BY DIRECT INSTRUMENTATION WITH THE AID OF KILLIAN'S TUBES.

Dr. Cornelius G. Coakley presented a paper reporting 6 cases of this nature and discussing the general mechanical problems involved. He had tried the Kirstein method of examination years ago but had given it up; but observing at Killian's clinic the case with which bronchoscope tubes were passed through the larynx it occurred to him that such a tube with a window on one side could be used for the removal of laryngeal papillomata. He had had opportunity to give the method a trial in six cases. In all a general anesthetic was used. Some time might be saved by cocoainizing the pharynx and larynx before the administration of the anesthetic. The patient should be placed on the back, the shoulders brought to the edge of the table and, supported by an assistant, allowed to hang over. The operator should sit on a low stool the height of which can be so adjusted that the eye was directly opposite the widely opened mouth. The tongue should be grasped with forceps and drawn out, thus raising the epiglottis and facilitating the introduction of the spatula beyond the tip of the epiglottis. The tongue is now allowed to fall back into the mouth and the spatula is easily passed directly into the supraglottic portion of the larynx. A good view of the cords is now readily obtained and any growth thereon can easily be removed by a straight forceps passed through the spatula. The Kirstein headlight has been the illuminating agent. It has been somewhat difficult to remove multiple neoplasms on account of obscuration of the field by blood and mucus in spite of frequent wiping away with cotton. Out of the six cases the result was satisfactory in 4. One proved to be malignant and required a thyrotomy, while in one the bulk of the growth appeared to be caught between the spatula and the anterior portion of the larynx.

Prof. Gustav Killian said that he had two cases under observation in which he had operated in the method described by Dr. Coakley. In such cases it is necessary to cocainize the larynx very thoroughly or it will contract from the contact of the tubes so that nothing can be seen. This method obviates laryngotomy and tracheotomy. If the patient can breathe sufficiently well to allow of general narcosis, the direct method of operating may be employed. In recurring cases arsenic should be given for a long time. Potassium iodide also seemed to have some power in preventing the recurrence of papillomata.

Dr. E. Fletcher Ingals, of Chicago, had had several successful cases by the direct method. In one case during operation the larynx began to close. The child could not breathe so he had to do a quick tracheotomy as he had no intubation tube. In general he was inclined to believe that tracheotomy was best in all cases in young children, though Dr. Coakley's experience had demonstrated the fact that it was not necessary.

Dr. J. Payson Clark, Boston, referred to a paper on this general subject presented by him to the Association some years ago and gave the later history of some of the cases therein referred to. He had used the direct method in removing the growths. He was still a partisan of tracheotomy as it gave the larynx perfect rest during which a papilloma was more likely to atrophy than when the child was using the larynx as a respiratory organ.

Dr. Emil Mayer, New York, spoke of some of the disadvantages of the tube with reference to the heat from the headlight. The attachment of the light to the handle of the spatula was a great improvement. His own experience as to recurrence had been the same as that of the preceding speakers.

The paper was further discussed by Drs. H. L. Swain, Casselberry, Coolidge, Lincoln, Langmaid, Hubbard, Delavan and Ingersoll. Discussion was closed by Dr. Coakley who stated his belief that cases of recurrence in children were cases in which new papillomatous areas occurred. Such would crop up in spite of all we could do. He certainly would not consider any cases as cured unless there was a freedom from return of the growth for several months. He believed, however, that if these cases were seen early it was often possible to avoid the deformity of an external operation, but one should not give an anesthetic without having a tracheotomy tube handy. He preferred to apply 10% cocaine before the general anesthetic was given, waiting sufficiently long for the cocaine to act. He was not sure of the efficacy of pure carbolic applications to the seat of the growths. It was at least harmless but he would not use it unless the patient was wearing a tube. He had used cocaine in connection with chloroform several times without bad results. He knew, however that such a combination was regarded by some as risky. A tracheotomy tube if worn some years would be likely to cause a certain amount of stricture though this might cause no trouble. Parents were naturally averse to having scars on their children's neck, especially with girls. On the other hand tracheotomy was distinctly of service in giving rest to the larynx.

OPHTHALMOLOGICAL MANIFESTATIONS OF LATENT DISEASE OF THE NOSE AND ITS ACCESSORY SINUSES.

DR. FRANCIS R. PACKARD reported a series of cases illustrating the relation between eye and nose conditions as suggested by the title of his paper. The examinations of the eyes had been made by Dr. W. C. Posey, of Philadelphia. Dr. Packard stated his belief that there should be more active correlation between the ophthalmologist and rhinologist in order to insure the recognition of this class of cases. Experience has shown that the ocular symptoms occurring as a result of sinus disease may variously affect the vision and visual field, orbit, lachrymal apparatus, lids, extra-ocular muscles, conjunctiva, cornea, pupil, uveal tract, and may lead to cataract, reflections, asthenopia and headaches and neuralgias. His series of nine cases reported bore out the foregoing statements. The truth of this theory of connection between the two organs was borne out by the results of treatment. Dr. Packard referred to various contributions on the subject by various authors.

DR. J. H. BRYAN, of Washington, D. C., had for some time been accustomed to have his sinus cases examined by an oculist and had seen external rectus paralysis from sphenoid disease, scotoma, narrowing of the visual field, etc.

DR. G. A. LELAND, Boston, stated that there were three cardinal symptoms of the eye condition that pointed directly to an intranasal origin,— astygmatism against the rule, ciliary reflex and narrowing of the color field. He gave the detailed history of one case of the nature described in Dr. Packard's paper.

DR. L.A. COFFIN, New York, said that the connection between eye and nose conditions was not yet sufficiently recognized even in special institutions. Patients operated on for sinus disease were often able to lay aside their glasses.

DR. F. C. COBB, Boston, said that in sinus disease conjunctivitis may arise from direct infection from nose to eye but with regard to astygmatic affections, there was little satisfactory evidence. There was a tremendous neurasthenic element in all these patients, and allowance ought to be made for this before we make positive statements as to the relations between the maladies of the two organs in question.

DR. H. P. MOSHER thought ptosis a rather unusual symptom of latent frontal sinus disease. He had, however, seen it once. He had come to the conclusion that the x-ray would clear up many cases of weakness of vision due to trouble in the sinuses or ethmoidal region. An ethmoidal condition might be revealed which had given no signs in the nose. Discussion was closed by Dr. Packard.

SECOND DAY, WEDNESDAY, MAY 8.

SESSION AT 10 A.M.

SPASM OF THE ESOPHAGUS.

DR. JOHN W. FARLOW, Boston, reported the case of a woman of fifty years who was subject to spasm of the esophagus and whose father and paternal uncle were subject to similar attacks. The patient herself had had a few attacks of discomfort of the throat while eating, and four years ago, while eating a piece of raw apple, became pale, looked distressed, put her hand to her throat and was evidently in great distress. Pain was felt in the lower part of the neck but did not extend to the back or arm. She was able to speak, and pulse and breathing were not affected. Was unable to swallow anything during the seizure. Hot applications to the neck gave comfort but did not relax the spasm. In about twenty minutes she felt relief from pain, raised some frothy mucus which had collected in her throat and the attack was over. Examination showed only a slight chronic pharyngitis and a moderate enlargement of the lingual tonsil. She went then for a year without a further seizure and the third attack did not come on for still another year. Massage of the neck was begun, cold compresses used and local treatment applied to the throat. She has now gone another year without an attack but the author admits that treatment may not have had any effect. He would ask, What is the nature of such attacks and how are they to be differentiated? Angina pectoris would cause great dyspnea, pain in chest radiating down the left arm and there would be changes in the pulse and breathing. These were all wanting in his patient. We consider esophageal spasm as more likely to occur in neurotic patients but this woman is not in the least neurotic. A further matter and the one of practical importance concerned measures of relief. The patient was unwilling to allow the use of any anesthetic which might have caused unconsciousness. A hypodermic of morphine might have relieved her, but in the two attacks in which Dr. Farlow saw her, she seemed hopeful that the spasm would soon relax and was loath to have morphine used. As she could not swallow and her mouth was full of saliva and mucus, he did not think that cocaine would have any effect. Emetine had been suggested in tablet form and the patient could carry the remedy with her, to be used at the onset of any further attack. Perhaps apomorphine in $\frac{1}{6}$ gr. hypodermic dose would be efficacious, but as it would require from five to twenty minutes to act, it might not really shorten the attack. Dr. Farlow asked for therapeutic suggestions from those present.

DR. H. L. SWAIN, New Haven, had had a recent case of the kind referred to by Dr. Farlow. His patient referred the origin of his spasm to a point on the left side of the throat. There would be a sort of cramp with pain and then until the throat relaxed nothing could be swallowed, even water. The sigmoid sinus was cocainized and an instrument passed down to a level just below the cricoid. Then the man was able to swallow. By the esophagoscope a round swelling was discovered on the left side about 25 cm. down from the teeth. A mild silver nitrate solution was applied but the patient did not report again and his later history was unknown. The condition seemed to be a cramp of the esophagus.

DR. W. E. CASSELBERRY, Chicago, wished that Dr. Farlow had tried cocaine. He had had several cases himself similar to the one reported, as to symptoms at least, and in these cocaine had done good service. Even if we are not able to apply the remedy directly to the seat of spasm enough exudes through near to the place of spasm to affect the muscles in the neighborhood.

DR. L. A. COFFIN thought that some of these cases were instances of disordered reflexes. In one case cure had resulted by the removal of adenoids. There might be various peripheral points from which the stimulus would come, it being expended in each case on the esophagus.

DR. E. FLETCHER INGALS, of Chicago, had had under observation for some weeks a case similar to Dr. Farlow's. The passage of bougies of large size gave relief. Cocaine might be used before passage, though his patient preferred its omission. General tonics and bromides in these cases were an adjuvant to treatment.

PROF. GUSTAV KILLIAN said it was necessary to exclude changes in other organs before making a diagnosis of local spasm. The latter might be primary or secondary. In one case it came from a diseased stomach. In other cases the patient eats too rapidly and does not masticate sufficiently. He had devised an

instrument to illustrate to the patient the effects of insufficient mastication. Such a demonstration had more effect on the patient's mind than any amount of general advice.

The president, Dr. A. W. de Roaldes, wished to call attention to the fact that some of these spasms might be secondary to disease of the nervous system. He had seen the condition in tabes. It might come on not only late in this malady in which clonic attacks were often noted but also in the early stages. In one of his patients the esophageal symptom was the initial evidence of tabes.

Dr. G. Hudson Makuen believed in the existence in many of these cases of a nervous or psychical element. The patients could not swallow because they thought they could not or were afraid they could not. They always did better while under a condition of mental exhilaration. This might arise from the constitutional effect of cocaine when applied rather than to the latter effect on the spasmodic factor. In one of his own patients there seemed to be a unilateral paresis of the pharyngeal muscles.

Dr. Farlow closed the discussion stating that while all that had been said was interesting no one had offered him any suggestions as to treatment of his own case. Exhilaration was not a factor in his own case nor was improper eating. If cocaine was applied when the mouth was full of saliva, it would probably fail to act. In his own patient he would feel loath to pass an instrument of any size down the esophagus, especially when the patient was gasping for breath. Methods of treatment which could be used in dispensary patients with frequent attacks could not be used with patients who went a long time between attacks and were in perfectly good health in the meantime. It was worthy of note that the father and uncle of his own patient were affected in the same way, also an aunt and a sister. In this instance there seemed to be some family peculiarity.

SOME CONSIDERATIONS RELATIVE TO SYSTEMIC INFECTION THROUGH THE TONSILLAR RING.

Paper by Dr. J. L. Goodale, of Boston, Mass.: Dr. Goodale referred to his paper on this topic read before the congress of 1906, and stated that during the past year he had continued his work along the same line. He called special attention to the part played by the system in resisting the invasion by micro-organisms. A series of cases had come under observation illustrating the possibility of the entrance of rheumatic poison through the tonsils. Removal of the latter had generally been followed by improvement, but in one case a continuation of joint symptoms was observed in association with throat symptoms. A detailed history was given of the case. The faucial tonsils are, of all points in the tonsillar ring, the vulnerable point, but after they are removed infection may occur through the lymphoid structures of the posterior pharyngeal wall. Tuberculous infection may occur through normal mucous membrane without leaving any trace discoverable either by the naked eye or by manipulation. In some of the obstinate cases in which infection seems to follow with as great frequency after operation as before it, it seems probable that the cause of frequent bacterial invasion is not attributable as much to a faulty distribution of lymphoid elements as to a predisposition to such infection on the part of the patient himself. Finally we must further study the part played by the host in such cases. When we are called to such a case as has been considered, we must consider not alone the alterations in the tonsils but evidences of lymphoid change in the vicinity. Even if the tissues appear normal we are not able to say that they may not have been in time past channels of entrance for micro-organisms. If the individual in his previous attacks of systemic disease has had coincident disturbances in the throat this fact becomes of great importance. If it is possible to test the opsonic index of the individual with reference to the germs suspected of etiological relation which have been recovered from the throat, confirmatory evidence would thereby be obtained.

Dr. W. E. Casselberry called attention to the chain of lymphatic follicles behind the posterior faucial pillars, the so-called pharyngitis lateralis. This participated in the usual inflammations of the pharyngeal lymphoid tissues. In his opinion it was responsible for some of the systemic infections, as rheumatism, endocarditis, etc. Such glands might be destroyed by the cautery. They often kept up trouble after the tonsils proper had been removed. It was often necessary to extend the cauterization up beyond the level of the velum palati and down into the pharynx.

Dr. Robert C. Myles, of New York, said that the tonsil projecting into the throat was the one to which most attention had been paid, but there were other kinds which were just as dangerous. The crpyts went down deep and there the chief sepsis occurred on account of the moderate amount of epithelium. By properly examining the cervical glands one could tell the pathology of the tonsils without looking at the throat. If the tonsil affection is very definite the glands would be hard. In proportion to their softness, the infection was likely to disappear. Twenty per cent of tonsillar affections were of this variety while 80% were of the palatal tonsil. Some of these tonsils to which he referred were incapable of extirpation, which was a serious matter. Such tonsils might extend three quarters of an inch into the palate. There was danger in operating of setting up cellulitis of the neck. The best course was to clean such a tonsil out and involute it. A certain amount of cervical adenitis might result from the salpingeal folds and they should not be overlooked. Adenoids might cause swelling of the glands in the post-cervical region. No consideration of any tonsil case was complete which ignored the amount of adenitis present. It was difficult to say how often such glands were tuberculous.

Dr. George L. Richards, Fall River, Mass., gave the history of one obstinate case. He had seen cases with periodical attacks of tonsillitis in which it was difficult in the intervals to note any excess of lymphoid tissue, even on separating the palatal folds. In regard to the nature of the glandular inflammation he had found it at times tuberculous, at other times not. Often a tonsillectomy should be followed by enucleation of the cervical glands.

Dr. Francke H. Bosworth, of New York, said that it was our duty to remove diseased lymphatics. Enlarged lymphatics did not necessarily call for removal. If we removed the mechanical condition in the pharynx, destroying the focus that entangled the germs, we did all we were called on to do. It was not our duty to dig out all the lymphoid tissue but to remove the pockets which were the source of the mischief. Invagination of the tonsil was a diseased condition, but unless there were pockets, the condition was not one of disease. The so-called palatal tonsil he did not believe to be an organ of the normal body. A large rounded tonsil projecting into the throat without any follicles did no harm.

Dr. F. C. Cobb said that the logical retention by pockets or anything else tending to obstruct flow from the tonsils would cause more disturbance than a mere inflammation of the tonsil or of the lymphoid tissue. The latter might be a normal protective. At times it was overcome by the invading organisms which gained access to the general circulation. It was a mistake

to obliterate normal tissue simply on the evidence that through it pathological germs occasionally gained access to the system. There was very little sepsis in acute tonsillitis. The tonsil took care of an enormous number of bacteria.

DR. EMIL MAYER called attention to a recent article by Jacobi, taking an entirely different standpoint from that of the theory that there was a direct infection beginning with the lymphatics of the throat.

DR. REGINALD H. FITZ, Boston, president of the Triennial Congress, was invited to participate in the discussion, and said that rheumatism was the disease which most interested the general practitioner so far as the present topic was concerned. Whatever the tonsil might do in some infections, it did not do the same in all. Certain peculiarities of one micro-organism might allow it to pass through the tonsil but perhaps this was not true of all micro-organisms. He did not know whether the result of tonsil extirpation had been determined with regard to its bearing on cases of multiple arthritis. Infections occurring after removal of the tonsils should be investigated in relation to those occurring before operation.

DR. MYLES said that he did not advocate removal of lymphatics when they were protective, but only when they were suppurating.

DR. J. N. MACKENZIE, of Baltimore, referred to some of the former theories as to the function of the tonsil.

The lust for tonsil operations had now reached its zenith. The laity had become infected with the zeal for removal. He thought that the matter of infection through the tonsils had been very much exaggerated. Dr. Goodale had beautifully pointed out the bacteriological side of the question but there was another side — the clinical. He was inclined to think that the modern total tonsillectomy was absolutely unnecessary and sometimes harmful. One should be guided in each case coming under observation by safe and sane conservatism and common sense.

DR. BOSWORTH referred to his statement made in London, twenty-seven years ago, that there were no tonsils in a healthy throat, and believed that the truth of this statement would soon be accepted by all practitioners. The tonsil described by anatomists represented a disease-process.

DR. GOODALE closed the discussion.

PROF. GUSTAV KILLIAN gave a demonstration of various new instruments devised by him for use in bronchoscopy and esophagoscopy, and a general discussion ensued on these operations.

DR. H. P. MOSHER was delighted to have had the opportunity of seeing these new devices. He preferred to have the light on the end of the tube so as to get it as near the foreign body as possible. He had noted that Professor Killian had had to put the suction tube inside the main tube so as to remove the mucus. With the plain, straight solid tube with a light at the end and a smaller tube set into the side of this tube to remove mucus, it was not necessary to introduce a special tube for this purpose. It was of great importance to know how many cases required an emergency tracheotomy tube after the manipulation of passing the tubes through the cords. Such a thing had been called for in this country and he would like to know of the experience in this respect in Germany.

DR. E. FLETCHER INGALS thought that in his practice he found it better to have the light at whichever end would give the most satisfaction. The light at the distal end did not always work well, no matter how bright it was. He preferred a suction tube, one that could be introduced through the main tube, as we needed all the room we could get; the larger the tube the better the lighting.

DR. EMIL MAYER said that very frequently blood would show itself in the mirror obstructing the view when the light was at the distal end. The holding of the light in the hand in the instrument shown was a great advantage. He thought it useless to practice on the cadaver. It was much better to work on the living dog. An injection of morphine kept the animal quiet. One then had conditions approaching clinical practice — the hot air in the face, the mucus and the little blood.

PROFESSOR KILLIAN, in closing the discussion, said that the diameter of an electric lamp must be at least 3 mm., and that the mirror in the tubes would in such cases obstruct most of them. He had found records of 116 cases of tracheotomy after bronchoscopy. In these cases the extraction was difficult and it was necessary to have the tube in position a long time. Personally he had never had such a case. If it was not possible to remove the foreign body through the larynx, we had to do a tracheotomy and also a lower bronchoscopy.

(To be continued.)

Book Reviews.

Outlines of Practical Sanitation, for students, physicians, and sanitarians, by DR. HARVEY B. BASHORE, Inspector for Pennsylvania Department of Health, etc. Pp. 208. New York: John Wiley & Sons. 1906.

This little book is exactly what it purports to be — an outline and not a treatise. It covers in a most sensible and satisfactory manner the chief topics which interest the sanitarian and also, as the preface states, the taxpayer and the citizen. It is wholly unpretentious and will serve to inspire the reader who is not an expert with a desire to go deeper into the subject of practical sanitation by further study.

Text-Book of Comparative General Pathology. For Practitioners and Students of Veterinary Medicine. By PROF. DR. TH. KITT, of Munich. Authorized translation by DR. W. W. CADBURY. Edited with notes and additional illustrations by DR. A. J. SMITH. Chicago: W. T. Keener & Co. 1906.

This translation of Kitt's authoritative work will form a valuable addition to the libraries of veterinary students. It contains much of interest to the student of human medicine. The morphological aspects of the subject are well presented, but special attention is given to disturbances of functions and to the etiology of disease. The author draws attention to the fact that " many of the discoveries of value to human medicine have been made from experimental studies upon animals, and the principles of general pathology particularly have been fundamentally proven by comparative study of the anatomy and physiology of animals, both branches of medicine, therefore drawing from the same sources and having a common field of work." The book is well illustrated and attractively bound.

The American Illustrated Medical Dictionary. By W. A. Newman Dorland, A.M., M.D., Assistant Obstetrician to the University of Pennsylvania Hospital. Fourth edition, revised and enlarged. Philadelphia and London: W. B. Saunders Co. 1906.

We are glad to welcome another edition of this excellent medical dictionary. In connection with the editions which have preceded this we have taken occasion to comment on the excellence of form and arrangement of this dictionary, which, from the standpoint of practicability, is one of the very best we have had occasion to use. Since the previous edition was published the text has been generally revised; new words have been added to the number of over 2,000; the text has been altered and improved, and the tables have been amplified. Particularly noticeable is the increase of illustrations through the addition of six colored plates, illustrating the subjects of appendicitis, diphtheria, gallstones, Leischman-Donovan bodies, measles and nephritis. We take pleasure in recommending this book, as we have before, to practitioners of medicine and others desirous of keeping abreast of the constantly changing terminology of the medical sciences.

Tics and their Treatment. By Henry Meige and E. Feindel. With a preface by Professor Brissaud. Translated and edited, with a critical appendix, by S. A. K. Wilson, M. A., M.B., B.Sc. 8vo, pp. xxii, 386. New York: William Wood and Co. 1907.

The work of Meige and Feindel appeared in French in 1902, and it has ever since been recognized by neurologists as one of the most important contributions to our knowledge of a class of somewhat obscure phenomena that has been published. To the authors we owe the extension of the term "tic" to a large class of semi-purposive movements and the distinction of these movements from the different forms of muscular spasm. To them, too, we are indebted for emphasizing more strongly the relation between the various forms of tic and mental instability. In this connection the confessions of a *tiqueur* which begin the volume will be found of the greatest interest. In addition to their work in demonstrating so clearly and so elaborately the nature of the tics and their great frequency, we are indebted to them still more for having devised a method of treatment in the nature of muscular re-education, which has in many instances effected a cure of a condition which was once regarded as incurable. The present translation reads smoothly and is in one way superior to the original French edition in that it adds various paragraphs from Meige's later monograph, *Les Tics*.

Practical Gynecology. A Comprehensive Textbook for Physicians and Students. By E. E. Montgomery, M.D., LL.D., Professor of Gynecology, Jefferson Medical College; Gynecologist to the Jefferson Medical College and St. Joseph's Hospitals; Consulting Gynecologist to the Philadelphia Lying-In Charity and the Kensington Hospital for Women. Third revised edition. 970 pages, 574 illustrations. Philadelphia: P. Blakiston's Son & Co. 1907.

This edition of Dr. Montgomery's textbook contains 81 pages more than the second edition and 151 more than the first edition. The table of contents occupies 14 pages and amounts to an index in its fullness, perhaps because of the peculiar classification. Here are the twenty chief headings: Introduction, Etiology, Diagnosis, Pelvic Examination, Animal Parasites, Abdominal Examination, Therapeutics, Medical Treatment, Local Therapeutics, Electricity, Embryology and Anatomy of the Genito-Urinary Organs of the Woman, Physiology, Malformations, Traumatisms, Inflammations, Inflammation of the Cervix and Body of the Uterus, Displacements of the Pelvic Organs, Genito-Urinary Hemorrhage, Extra-Uterine Pregnancy, Genital Tumors.

It is difficult to account for the position of the heading Animal Parasites, especially as under it comes a lengthy description of blood examination and exploration of the urethra, bladder and ureters. Under Therapeutics comes first the description of the technique of abdominal operations. The student would soon be lost if it were not for this lengthy table of contents and a very good index. There are some new illustrations in this edition. Most of these plates are worn and are much less distinct than in the first edition, especially those depicting microscopic specimens. We are glad to see a correct illustration of the Sims position, seldom found in textbooks on gynecology. A little embryology has been added to the chapter on the anatomy of the female genito-urinary organs and changes in the illustrations are to be noted here. Vesico-vaginal fistula was removed from the chapter on malformations and put among the traumatisms in the second edition. The figures as a whole are not arranged so as to help the reader as much as they were in the first edition. For instance, those illustrating the relative zones of dullness and resonance in ascites and in ovarian tumors, instead of being on pages facing each other where they may be compared, are back to back. The same confusing multiplicity of operations for the repair of lacerations of the perineum observed in the first edition is to be found in this. The Gilliam-Ferguson operation for shortening the round ligaments with Montgomery's modification is introduced into the chapter on retroversion; this in the way of improvement and bringing the book up to date. On the other hand, many archaic operations, such as the Stolz pursestring operation on the anterior wall of the vagina and the Sims operation for anteversion still find a place in the book.

The portions of this book that mirror the author's extensive experience are of great value to the student and practitioner, but the complications and the illustrations, to say nothing of the classification, leave much to be desired when compared with other recent works of a similar character.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 12, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

THE ALARMIST PHYSICIAN.

THE attitude of the physician toward his patients is no doubt usually determined by his personality and general attitude toward his professional work. It is difficult, if not impossible, to lay down any laws by which a physician should be governed in the treatment of his patients outside of the prescription of drugs and remedial agents. No doubt, human nature is much the same now as it always has been, but considerable recent discussion has again called attention to the relation of the physician to his patient, and it is, perhaps, worth while to reconsider the matter from the standpoint of various recent observations.

A type of physician which still exists, but which on the whole we are inclined to think is becoming rarer, is the alarmist,— a man whose training and attitude of mind are such that he looks with natural pessimism on conditions of illness, however vague his special knowledge on the subject may be. We are still continually being brought in contact with men who give a bad prognosis, not so much from a careful weighing of all the facts in the case as from a general disposition of mind which is so impressed with the grewsomeness of life that it finds it almost impossible to look upon the bright side. It is quite astonishing at times to meet with physicians who calmly and conscientiously condemn their patients to lives of invalidism or premature death on grounds which to another man would permit of no such gloomy outlook. This attitude of mind, we are convinced, is far too prevalent. It requires no wide experience to meet with patients continually who are cast down with discouragement because of a hopeless prognosis which has been made of their condition, often by men of high standing in the profession.

We are, no doubt, too prone to forget the deep significance which patients are disposed to attach to the statements of their physicians and the manifold neurotic conditions which may arise in consequence of such statements. It is therefore altogether desirable that we should know clearly whereof we speak before we make any dogmatic assertions of a depressing sort to our over-solicitous and sensitive patients. The harm which is done through carelessness in this regard is not to be lightly estimated. Cases, no doubt, will suggest themselves to any physician of wide practice in which an inadvertent, or possibly a considered, statement on the part of a physician has led to most distressing results for the peace of mind of the patient.

There are certain matters which seem sufficiently apparent in the present state of our knowledge to permit of dogmatic statement. The first is that in any individual case we know extremely little about prognosis, and certainly have no right to be dogmatic as to the duration of life. No more striking example of this could be adduced than the change which has come over the medical profession, and secondarily over the laity, in regard to the outcome of tuberculosis. The horror of inevitable and more or less speedy death has been replaced by a feeling of hopefulness which now permeates every element of society and has practically robbed the disease of its terror. The same is true in lesser degree of many other diseases. The prognosis of various affections has absolutely changed in the lifetime of many physicians now living. In view of these facts, it is rather the part of ignorance than of knowledge to condemn a person to death, even if suffering from a disease which is ordinarily regarded as fatal. As a practical policy it is well always to give the patient the benefit of the doubt.

In the second place, even if we think we are practically sure of our knowledge regarding the prognosis of any affection, it is manifestly unwise in a great majority of cases to express that opinion to our patients. The world is sufficiently full of misery without adding any more which can possibly be avoided. Our honesty and the good of the community will not suffer thereby. Dr. F. C. Shattuck has recently admirably summed up the situation in an address before the graduating class in medicine of the Yale Medical School. He says in part: "What is truth? In matters medical we are dealing with x, y and z, and we must never forget that our opinion does

not necessarily represent the truth. The truth as we see it may not be the truth itself. In telling the truth as the truth, we should be very sure that it is the truth, especially if in so doing we condemn the patient to an incurable and painful malady. There is generally a near friend or relative to whom we can speak frankly if we like, expressing our fears, from which we should not be too ready to take counsel. But, apart from our liability to error, it seems to me that every practitioner now and then meets a case in which neither silence nor skillful evasion avail, and in which telling the truth is sheer cruelty. . . . Doubtless, ordinarily, the truth, which may be stated with brutal frankness or with delicate consideration, is best for all concerned, especially if it be served with the saving grace of 'as I see it,' or its equivalent."

As a guide to conduct we need hardly go further than this, nor can the most captious critic maintain that our morals will suffer thereby.

POLIOMYELITIS IN NEW YORK.

At present nearly one hunderd cases of poliomyelitis are being treated at the Hospital for Ruptured and Crippled, and in view of the prevalence in the city of this disease, so disastrous in its permanent results, and also of the fact that outbreaks of the affection have recently occurred in several localities within a radius of two hundred miles of New York, a systematic campaign against the disease has been undertaken. The plan of this has been mapped out by Dr. J. F. Terriberry, neurologist to the hospital mentioned above. Taking it as a highly probable point that the disease is due to a specific germ, a circular has been prepared, to be sent out to physicians generally, in which the request is made for such reports as would do much toward establishing at least the usual surroundings in which the disease occurs most frequently, and thus afford some idea of the conditions favorable to the development and growth of the supposed morbific organisms. Among the conditions, which it is suggested should be reported upon, are the following: Temperature, humidity and analogous conditions; natural peculiarities of the region, whether urban or rural, and with especial emphasis as to sunlight; whether epidemics of other diseases were occurring at the same time; the amount of area covered by the outbreak; the source of the water supply. The query in reference to other epidemics was occasioned by a recent report from Ridgway, Penn., to the effect that simultaneously with the infantile paralysis, typhoid fever and epidemic cerebrospinal meningitis were prevalent. In addition to the cases now under treatment at the Hospital for Ruptured and Crippled a large number are being treated at the New York Orthopedic Dispensary and Hospital and other institutions in Manhattan and Brooklyn. A great handicap in the way of successful treatment is that the cases are not brought to the hospital in the acute stage. It is only when the febrile condition has run its course, and the characteristic phenomenon, the muscular paralysis, has developed that the patients are brought, and permanent disability is very liable to result.

BLINDNESS FROM BIRTH.

The recent meeting in Boston of the American Association of Workers for the Blind was productive of the dissemination of much knowledge regarding this unfortunate class which is not generally known. One of the statements made was that nearly 70% of the existing cases of blindness might have been prevented, since the blindness was due to an ophthalmia at birth which naturally is avoidable in the great majority of cases. Could the infants be cared for at this early stage and the proper remedy supplied, there is no doubt that more than half the blindness in the world might be entirely obviated. From a theoretical standpoint this is an easy statement to make, but to educate the people and to put laws in operation which would control this disease of early life, are matters somewhat difficult of accomplishment. In Prussia it is said a law exists providing that every case of ophthalmia or conjunctivitis during the first two weeks of life must be reported in the same way as other contagious diseases. Could such a law be enforced, no doubt its results would be far reaching in their benefit, and there seems to be no inherent reason why it should not be, provided both the laity and physicians could be educated up to a recognition of its necessity. As in all other classes of human defects, the state is ultimately burdened with the support of many of the blind. For practical reasons, therefore, quite apart from humanitarian motives, it is altogether desirable that definite and immediate action be taken to minimize this largely preventable evil.

MEDICAL NOTES.

Cholera in St. Petersburg. — Cholera is reported as epidemic in St. Petersburg.

SLEEPING SICKNESS. — Favorable reports come from South Africa relating to Professor Koch's investigations on sleeping sickness. Excellent results are said to have followed the treatment which Koch and his assistants have instituted, and he is being well received by the native population.

CANADIAN JOURNAL OF MEDICINE AND SURGERY. — The current number of the *Canadian Journal of Medicine and Surgery* is this year published in connection with the meeting in Montreal of the Canadian Medical Association. It is an elaborate number, with many illustrations, which are particularly interesting from the fact that they picture various hospitals, sanatoria and various institutions in Canada, as well as some of the most striking scenery within its confines.

PLAGUE IN SAN FRANCISCO. — Owing to the continuance of plague in San Francisco, it is stated that the Public Health and Marine-Hospital Service has been given charge of measures to stamp out the disease. This step has been taken on the initiative of the mayor of San Francisco. It has been recommended that a hospital in which there has been a number of plague cases should be burned. A spread of the disease is not anticipated.

TRANSMISSION OF CANCER.— The subject of the infection of houses with cancer has again come up for discussion in Paris. A census is said to be in progress to investigate houses in which persons have died of cancer. For many years the possibility of infection of dwelling places has been entertained, and, in fact, was one of the matters which led to the theory of the infectiousness of the disease by means of micro-organisms.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Sept. 11, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 15, scarlatina 26, typhoid fever 28, measles 14, tuberculosis 41, smallpox 0.

The death-rate of the reported deaths for the week ending Sept. 11, 1907, was 19.62.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, Sept. 7, 1907, was 232, against 228 the corresponding week of last year, showing an increase of 4 deaths and making the death-rate for the week 19.85. Of this number 122 were males and 110 were females; 223 were white and 9 colored; 160 were born in the United States, 66 in foreign countries and 6 unknown; 52 were of American parentage, 157 of foreign parentage and 23 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 29 cases and 2 deaths; scarlatina, 29 cases and 0 deaths; typhoid fever, 21 cases and 1 death; measles, 7 cases and 0 deaths; tuberculosis, 38 cases and 23 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 11, whooping cough 0, heart disease 15, bronchitis 2 and marasmus 12. There were 7 deaths from violent causes. The number of children who died under one year was 93; the number under five years, 106. The number of persons who died over sixty years of age was 34. The deaths in public institutions were 89.

There was 1 case and 1 death reported from cerebrospinal diseases during the week.

ADDITION TO ST. ELIZABETH'S HOSPITAL. — The St. Elizabeth's Hospital Corporation, of Boston, has secured property adjoining the hospital which will be improved for purposes of the institution.

BEQUESTS TO HOSPITALS. — By the will of the late Mrs. Margaret E. Langdell, of Cambridge, Mass., the Cambridge Hospital receives $10,000 for the establishment of two free beds, and the Holy Ghost Hospital for Incurables, also in Cambridge, receives $10,000 without specification as to its use.

FINE FOR NEGLECT OF QUARANTINE REGULATIONS. — On Thursday, Aug. 22, 1907, in the Municipal Court of Boston, the captain of the fishing vessel, *Flora S. Nickerson,* was fined twenty-five dollars for violation of quarantine regulations of the port of Boston adopted by the local Board of Health. His offence consisted in bringing a case of smallpox into port without anchoring for inspection at the quarantine station.

STATE COMMISSION ON CONSUMPTION. —Dr. Arthur T. Cabot has been appointed chairman of the new Massachusetts State Commission on Consumption, the functions of which are to attend to the building of hospitals and to disseminate information in regard to methods of overcoming the disease. It will be remembered that when Dr. Cabot was president of The Massachusetts Medical Society he took a particularly active interest in the matter of tuberculosis and did much pioneer work toward devising means of combating the disease.

Surgical Appliances for Factories and Shops. — In compliance with an Act of the Massachusetts Legislature the Boston Board of Health requires the following medical and surgical appliances to be kept and maintained by factories and shops in Boston: 2 elastic tourniquets (minimum, 24 inches); 2 rolls ½-inch zinc oxide adhesive plaster; 2 rolls 2-inch adhesive plaster; 4 dozen gauze bandages, assorted sizes, from 1 to 4 inches; 1 lb. absorbent cotton; 1 yard sterile gauze; 1 dozen emergency slings; 5 yards Canton flannel (used with carron oil for burns); 1 pair scissors, straight (2½-inch blade); 500 tablets 1¾-gr. corrosive sublimate and citric acid; 6 whitewood strips, 40 x 4 x 3-16; 2 pillows; 1 package of pins; 3 dozen safety pins; 8 oz. spirits ammonia, aromatic (rubber stopple); 1 gallon carron oil; 1 pint brandy; 1 basin.

Physical Training, Boston Public Schools. — Dr. Thomas F. Harrington, formerly of Lowell and now of Boston, has been appointed director of athletics and physical training in the Boston public schools. Dr. Margaret E. Carley has been appointed supervisor of nurses, with twenty assistants. The School Board has for some time been preparing to reorganize the department of physical training, and it is fortunate in having secured Dr. Harrington to undertake this work. Dr. Harrington is to have charge of this reorganization with such assistants as he may require. He is also to have charge of the vacation schools and the playgrounds, which were not included in the duties of his predecessor. Dr. Harrington is a graduate of the Harvard Medical School and was the author of the recently published history of the school.

Opening of Out-Patient Department, Boston Consumptives' Hospital. — The trustees of the Boston Consumptives' Hospital on Sept. 11 opened an out-patient department for the treatment of pulmonary tuberculosis at 13 Burroughs Place, Boston. For the present this out-patient department will be opened for the examination and treatment of patients on Mondays, Wednesdays and Fridays at 10 A.M. It is intended later to open the department during the evening. Persons who have any reason to believe that they are threatened with consumption are urged to present themselves at the out-patient department for examination, and physicians are requested to send such patients as they deem need attention. Persons desiring admission to the consumptives' wards at the Holy Ghost Hospital, Carney Hospital and St. Monica's Home should present themselves at the out-patient department on Mondays, Wednesdays and Fridays at 11 A.M.

NEW YORK.

Boiling of City Water. — On account of the lowness in the reservoirs, due to the lack of rain during the past summer, which naturally tends to the concentration of impurities, President Darlington of the Health Department has advised that for the present the city water should be boiled before drinking. The mortality from diarrheal diseases continues considerably higher than at the same season last year.

A Case of Simulation. — Justice Brady of the New York Supreme Court has affirmed the sentence of Alpheus S. Frank, an attorney, who was recently convicted of subornation of perjury by a jury in the Westchester County Court, and sentenced by Judge Platt to a term of three years in Sing Sing prison. Frank, who was formerly a chief clerk for the claim department of the New York City Railway Company, was found guilty of preparing a fake trolley suit brought by one Mae Herbert, of New York, against that company for damages for personal injuries. On the trial it was shown that Miss Herbert had sued under a false name, as she was in reality the wife of Abbott Woods, who was conductor of the car from which she claimed to have fallen. It was also shown that the woman was formerly a circus tumbler and contortionist, which enabled her to leap from cars at full speed without hurting herself. She had an old injury, received by falling from a trapeze, which she exhibited for the purpose of proving her case; and it is said that she had figured in several successful suits of the kind before her identity was discovered.

Contamination of Hudson River Water. — Pursuant to an order issued by Governor Hughes on Aug. 10, a commission of sanitary engineers has been making an investigation of the waters of the upper Hudson, and its report, together with the findings observed in the State Hygienic Laboratory at Albany, which was communicated to the State Health Department on Sept. 1, shows that pollution of these waters is so extensive as to constitute a nuisance. The investigation covered the counties of Washington, Warren and Saratoga, and it was found that the upper Hudson River and its tributaries were polluted by the industrial waste from thirty-five pulp and paper mills, ten knitting mills, eight woollen mills, seven wall-paper mills, and three cotton-

print mills, in the states of New York, Vermont and Massachusetts, and by the domestic sewage of a population of some 79,000 people. The total pollution from industrial waste is reported to amount to about 1,460,000 pounds daily.

MEETING OF AMERICAN PHARMACEUTICAL ASSOCIATION. — The fifty-fifth annual meeting of the American Pharmaceutical Association was held at the Hotel Astor during the first week of September, this being the first time for forty years that the society had met in New York. On Monday, the opening day, addresses were made by the president, Leo Eliel, of South Bend, Ind., and a number of others. Among those who spoke were: Dr. S. Solis Cohen, of Philadelphia, who presented the greetings of the American Medical Association; Dr. Harvey W. Wiley, of the Bureau of Chemistry, United States Department of Agriculture, who stated that the Pure Food and Drug Law was passed because it had the power of the great organizations behind it; Prof. José Diaz, of Havana; Paul J. Waldner, of the Naval Laboratory, Brooklyn; Prof. W. M. Searby, of the San Francisco College of Pharmacy, and Dr. William C. Alpus. The latter said that during the last year over $200,000 worth of pharmaceutical supplies had been exported and imported by the United States. On Sept. 3, the following officers were elected: President, William M. Searby, California; first vice-president, Oscar Oldberg, Chicago; second vice-president, Prof. Henry H. Rusly, New York College of Pharmacy, Columbia University; third vice-president, Charles Holzhauer, Newark, N. J.; general secretary, Prof. Charles Gaspari, Jr., Baltimore College of Pharmacy, University of Maryland; treasurer, S. A. D. Sheppard, Boston. Hot Springs, Ark., was chosen as the next place of meeting.

1. Schmeiden describes Bier's treatment of tuberculosis of the joints by hyperemia, as used by himself. His method depends on the recognition that inflammatory reaction in the infected parts is an effort of the system to protect itself against the bacilli, and that there is benefit in increasing artificially redness, swelling, and heat of the part. For this purpose he uses the blood by increasing hyperemia and at the same time decreasing the flow of blood to the joint. The hyperemia is produced by a broad rubber bandage, applying it evenly about the limb proximally and not too close to the joint. The bandage must not cause pain at the point of constriction or in the joint, and the extremity must remain warm and the pulse unchanged. The bandage is applied for a few hours per day with intermissions. The joint must not be kept in fixation, while violent motion is not allowable. The object is to obtain anatomical healing, with mobility of the joint. Pain and inflammatory contractures disappear, active and passive motions become possible, swelling subsides, large fungous masses are absorbed, and fistulæ close. That cold abscesses form is no contra-indication to treatment; this is only the attempt of nature to throw off the dead tissues. This treatment is so simple that it may be applied by the patient himself, and he may attend clinics. Resection is usually unnecessary. The best results are obtained in the shoulder, elbow, wrist and small joints. The hip and knee cannot be successfully treated. Exudative inflammation is not treated by hyperemia. Cupping glasses are used for the breast, for gland and fistulæ.

8. Meyer has used Bier's method of hyperemia in many conditions. He finds it especially satisfactory in bone and joint tuberculosis. Its advantages are the rapid alleviation of pain, the excellent ultimate functional results, and the possibility of home treatment, or even while at work. It has been found that the shorter and firmer application of the constricting bandage, *i. e.*, one hour in the morning and one to two hours at night, is even more efficacious than the prolonged use, *i. e.*, for six to twelve hours continuously. The disadvantages are the necessity of care in the details of application and the long time required, at least several months, for cures.

Meyer has secured gratifying results in a multitude of acute surgical infections. He uses glass cups on boils and carbuncles and proposes to treat meningitis by a band constricting the neck.

9. Wright gives a summary of the principles of his so-called vaccine treatment. He discusses the theory of opsonins and the action of vaccines. He reiterates the advantages of this treatment in localized infections, recording two cures in a series of six cases of streptococcal septicemia. [R. I. L.]

1. Barker's article is a concise description of the laboratories of the Johns Hopkins Hospital, their organization and development. The value of clinical and also of research laboratories in close connection with the medical clinic is clearly set forth. This number of the *Bulletin* publishes the reports of work done in these laboratories for the past year.

2. Morris reports his observations upon nuclear bodies, first described by Howell, as occurring in the blood of cats after severe hemorrhage. Morris has seen these bodies in experimental anemia of rabbits, in a case of pernicious anemia in man, in the blood of a human embryo and in human blood in other conditions in which nucleated red blood corpuscles were present. It is thought possible that they result either from atrophy of the nucleus or as products of the nucleus.

3. In a second paper Morris demonstrates that the liver and spleen in severe anemias may resume their embryonic rôle as blood-forming organs. This it is probably to be regarded as an effort to increase blood production to compensate an abnormal blood destruction.

4. Hinman and Sladen publish a critical description of methods which have been used to determine the time of coagulation of blood. Least liable to objections they find the Brodie-Russell method as modified by Boggs and an original simple modification of Milian's slide method. This latter method, from its simplicity and accuracy, deserves wide recognition. It is performed by simply touching a drop of blood from the ear with the under side of a glass slide held horizontally so that a drop 4 to 5 mm. in diameter shall adhere to the slide and observing the time from the instant that the drop has begun to flow from the ear until changing the slide from horizontal to vertical position no longer causes a change in contour of the drop. The diameter of the drop on the slide is important, since the average normal coagulation time for a drop of 4 mm. is about 6 minutes and for a drop of 5 mm. is about 9 minutes. The readings agree in general with those made in the same cases by the Boggs Brodie-Russell instrument. Coagulation tests were made in a number of pathological cases, the greatest delay in coagulation time noted being in jaundice, due to malignant disease. Experiments were made as to the influence of calcium salts in reducing the coagulation time. These were found to have marked effect in increasing the coagulability for three to five days, when given in doses of 15 gr. of the lactate, in syrup or in capsules, four times a day. When this dose had ceased to have effect, increasing the dose every three to five days maintained the low coagulation time for a longer period. Sodium citrate, on the other hand, seemed to increase coagulation time.

6 and 7. The articles of Cole and Meakins and of Jeans record observations in the treatment of gonorrheal arthritis and of tuberculous infections by bacterial vaccines and tuberculin (TR) respectively, controlled by the opsonic index. The results of treatment in both instances are considered sufficiently favorable to warrant further investigation. The value of the opsonic index as a means of control is thought to be open to question.

8. Moss reports the results of experiments with rabbits to determine the effect of injections of bacterial vaccines and of living bacteria upon the opsonic content of the blood. He determined the opsonic index by Wright's method and the phagocytic index advocated by other investigators; he also investigated the action of the sera obtained in different degrees of dilution. The opsonic index seemed to give the most reliable results, but throughout the work so many inconsistencies of results and so many sources of error as yet not overcome were encountered, that it is concluded that none of the present methods of estimating the opsonic content of the blood are sufficiently accurate to be of practical value. Furthermore, in spite of necessary inexactness of the tests, it is clear that no high degree of opsonic immunity, such as is possible in antitoxic and bactericidal immunity, can be produced in rabbits by ordinary inoculation procedures with staphylococcus aureus.

11. Meakins has applied the procedure of testing for "fixation of the complement" to meningococcus and gonococcus infections with positive results in all of six cases except one (possibly a misprint in the table). The test is performed by mixing (1) the patient's serum, in various dilutions, inactivated by heat; (2) bacterial emulsion, and (3) normal serum containing complement, and incubating the mixture for half an hour. In positive cases the complement is bound to the bacteria receptors by the antibodies of the patient's serum, and on the addition of red blood corpuscles and inactivated hemolytic serum the complement necessary to hemolysis being "fixed" in this union, no hemolysis can occur. In the control cases, on the other hand, the same process results in hemolysis. The technic is too complicated for use in routine diagnosis, but in the study of special cases the procedure is believed to be of value.

14. Hirschfelder describes various methods of estimating minimal blood pressure. That of Erlanger is by far the most accurate, but the bulk and expense of the apparatus preclude its general use. Other methods are less reliable. That of Strasburger, widely employed in Germany, is worthy of some attention. According to this, the pressure on the upper arm is measured up to which the volume of the radial pulse is maximal. In skilled hands Hirschfelder admits that the results of this method are accurate. To insure uniform palpation it is well to rest the tips of the finger against the radius and to feel the artery with the ball of the finger. The average of not less than six readings should be taken for the final result. For maximal

pressures the Riva-Rocci instrument with the broad band may be used; readings with this average 5 mm. lower than with the Erlanger apparatus. The practical importance of these readings lies in the fact that the maximal pressure is a measure of the intraventricular pressure of the heart, and the minimal pressure is a measure of the resistance in the vessels. The dicrotic pulse of typhoid is to be attributed to peripheral dilatation with somewhat increased heart action.

17. Barker and Voegtlin report results of an investigation of the metabolism of a case of so-called phosphatic diabetes. The phosphorus excreted was found to be in excess, especially the organic phosphorus. The nitrogen excretion was extremely high. Calcium was excreted in excessive amounts, whereas the magnesium metabolism was normal. The acidity of the urine was variable, but at times very high, especially from organic acids which could not be identified. No acetone, diacetic or lactic acids were present. Tests for alimentary glycosuria were negative.

20. Baer calls attention to the fact, demonstrated by Finney, Codman and others, that causes of limited motion of the shoulder joint are not necessarily in the joint proper, but may lie in changes in the subdeltoid bursa. In acute inflammation of this bursa the treatment is that of any bursitis plus putting the arm at rest. In chronic cases, in which the bursa has become a mass of fibrous tissue, simple breaking up of adhesions under an anesthetic is not considered sufficient. Baer advocates incision and complete removal of the remains of the bursa. He reports four successful cases of this operation. [F. W. P.]

8. KELYNACK, T. N. *Tuberculosis among School Children.*

3. There are some 28 cases of this disease on record. The leading features are: (1) aplasia of clavicles; (2) exaggerated development of the transverse diameter of the cranium; (3) delay in ossification of the fontanelles; and (4) hereditary transmission. In other words, a hereditary general bony defect with predominance on a certain bone group. Abram's case had complete absence of any bony tissue in the clavicle, open fontanelles, and typical head. There was no hereditary element traced. His case was a boy of sixteen years, four feet and a half tall, generally stunted. Yet he was muscularly strong and intelligent.

5. Moynihan gives his enthusiastic approval to the continuous administration of salt solution by rectum, not only in acute peritonitis, but also after surgery on the stomach. He allows the fluid to flow at the rate of one pint an hour. He has given as much as sixteen pints in twenty-four hours, and twenty-nine pints during a period of three days. He considers that this method is safe and easily borne by patients, that it effects a remarkable change in their appearance and prospects for recovery after serious abdominal operations, and that the retention of such large quantities of fluid does not throw too much of a strain on the kidneys. [R. I. L.]

9. *LUBLINSKI. *Glandular Fever.*
10. *GROSSMANN, M. *Bronchospasm.*
11. KATZENSTEIN, J. *The Thoracic and Falsetto Voice.* (To be continued.)

1. Baümler reports two cases in each of which there was congenital agenesia of one lung, without any deformity of the thorax and no interference with the normal development of the body. This illustrates the power of the organs of the body to adapt themselves to abnormal conditions, and yet preserve their function. It seems to show that the bony thorax has a considerable inherent power of development, independent of the organs within. In most acquired pulmonary conditions this is hindered by the development and subsequent contraction of fibrous adhesions. That this is not always the case, however, is illustrated by a third case of fibroid phthisis of twenty-five years' duration, in a woman of thirty-five, in whom there was no deformity of the thorax.

2. Bouchard emphasizes the importance of gonorrhea as an etiologic factor in many cases of spinal arthritis, especially the milder types, affecting the cervical and dorsal vertebræ. It may develop coincident with the urethritis or long after. In the latter cases often there has been a persistence of gonococci in the genital adnexa, without local symptoms.

3. Weichselbaum has studied three epidemics of febris miliaris (Schweissfriesel or sweating fever). This disease suddenly appears in epidemic form, localized to a small region. Its duration is short. It affects largely adults between twenty and fifty and females in very large proportion. It usually appears in damp, warm weather. Its chief characteristics are fever, sweating and a papulovesicular exanthem. Weichselbaum considers it a disease *sui generis*. The subcutaneous emphysema, which so often appears post-mortem in these cases, is due to the Bacillus aërogenes capsulatus (Welch), but Weichselbaum does not think there is any proved etiological relation between this organism and the disease. The skin lesions are inflammatory in nature, not the result of sweat retention. The mortality in these three epidemics was 5.9%, 32.3% and 16%, respectively. Weichselbaum autopsied four cases. The lesions were those common to acute infectious diseases. The disease is contagious in only a very limited degree. Its etiology remains unknown.

4. Hochenegg calls attention to the occurrence of varicocele as a diagnostic sign of malignant tumor of the kidney in the male. It occurs on the same side as the tumor and differs from idiopathic varicocele in appearing rapidly at a more advanced age, in being less painful and in not disappearing in the prone position. It is due to tumor growth in the spermatic vein, pressure from metas-

tases about it, direct compression of the vein by the renal tumor, or a kink in it, due to displacement of the kidney. If caused in the last two ways, the varicocele subsides in the knee-elbow position, or when the tumor mass is normally moved. If due to the first two causes, it does not subside in these positions and this is a contra-indication to operation, since it indicates wide extension of the tumor.

7. The seriousness of tuberculous laryngitis as a complication of pulmonary tuberculosis is known to all who deal with the tuberculosis problem. Burger insists on the importance of local treatment of the throat, by surgical methods, if necessary. Without this, general sanatorium treatment not infrequently ameliorates the pulmonary condition, while the throat grows worse. The results of local treatment of the throat are really quite good and under these conditions there is a much better chance of the patient's ultimate recovery.

9. Lublinski does not regard "glandular fever" as a distinct disease entity; rather it is a septicopyemic condition secondary to various conditions, but very often accompanying an acute inflammation of the pharyngeal tonsil. The streptococcus is most frequently the causal organism, though other bacteria may be associated.

10. The sudden appearance and disappearance of certain forms of dyspnea early gave rise to the assumption of bronchial spasm as the cause. Especially has it been assumed that a spasmodic contraction of the bronchial muscle coat caused asthmatic attacks. The existence of smooth muscle in the bronchi is almost the only fact in support of this view. Some experimental work would seem to lend probability to the theory, but Grossmann, in a long, critical review of this, decides that experimental work does not accord with this theory, but rather favors disturbances in the pulmonary circulation as the cause.

3. Eichler says that the diagnosis of pancreas disease is always difficult and often impossible, and that it is not made in more than 50% of the cases. Despite the amount of work, which has lately been done on the resorption of proteids, carbohydrates and fats in diseased conditions of the pancreas, nothing of great moment in the diagnosis of these conditions has resulted. Sahli's "glutoid reaction" has been a step in advance, and a prompt reaction is now regarded as proof that the pancreas is not diseased; but a delayed reaction cannot be taken as proof of disease. Schmidt's new test, depending on the fact that the pancreatic juice dissolves the nuclei of meat — is also useful only in a negative way. The best-known change in the urine in diseases of the pancreas is the appearance of sugar; still this is not constant and in many cases absent. Often albumin, rarely fat, and extremely rarely maltose are found in the urine. A few years ago Cummidge described a new and complicated method of urine examination in cases of suspected pancreas disease and claimed that his method was of great diagnostic importance. The author carried out this procedure on the urines of three dogs, in each of which pancreatic lesions had been induced, and found Cummidge's test positive in all three. Several theories have been advanced as to the reason of this reaction in the urine, none of which seem satisfactory. The whole subject needs more careful attention and needs to be worked out more thoroughly. The important fact remains, however, that a positive reaction with Cummidge's test seems to point directly towards a pathological condition in the pancreas.

8. Bosse, B. *Lumbar Anaesthesia in its Modern Form.* (Concluded.)

1. Jurasz states that, while tuberculosis of the larynx is a very obstinate and resistant affection, it can be cured by energetic local and general measures. The treatment of the pulmonary condition must, of course, go hand in hand with that of the larynx. Vocal rest is of the first importance, the so-called "silence cure." Cough should be controlled by narcotics. Local treatment varies, from painting with astringents in mild cases to curetting or cauterizing and applying lactic acid in full strength. These procedures should be repeated again and again. Great patience and perseverance are required, and local measures are indispensable. No such case should be sent to a sanatorium unless proper throat treatment can be given. Palliative surgical measures are often a great relief. Tracheotomy often causes much improvement through rest to the larynx. Direct sunlight, reflected for hours at a time into the larynx by means of mirrors, is more beneficial than the Röntgen rays. Passive congestion produced by constricting the neck by rubber bands does much good, by relieving both pain and cough.

2. Lesser discusses syphilis in the light of the discoveries of the past year, claiming that great advances have been made in its rational treatment. The ability to detect the spirocheta pallida makes it possible to excise the primary lesion before the appearance of the secondary eruption, and to start the treatment early. This early treatment consists of mercury inunctions supplemented by local injections of corrosive sublimate, 0.5 cc. of a 1% solution, directly into the chancre, with or without the application of a mercuric salve. As a rule, no further manifestations of syphilis develop, but if they are observed they follow much sooner than usual, within six to twelve weeks, and when they appear are much less pronounced and fewer than usual. It is too early to tell surely whether this prompt treatment cures completely or not, and efforts are being made everywhere to discover new remedies. The most important of these is the sodium anilin-arsenate (atoxyl). In Lesser's experience it has a powerful action on the infectious agent, but is toxic to a high degree, and symptoms of intolerance are observed after a variable number of injections. These symptoms include gastro-intestinal pain, nausea, vomiting, general malaise, fainting, chilliness and albuminuria. The drug has a cumulative action, so the effect can be kept up with reducing doses. Its action is especially striking in malignant and ulcerating forms. The ordinary secondary associated lesions seem to be less influenced, but can be cured if the drug be given long enough. Owing to its toxic properties it probably will never take the place of mercury, but will aid us greatly in combating certain forms of the disease, and in those cases which show a marked idiosyncrasy to mercuric preparations.

4. Grawitz reports a case of Addison's disease, which he has been following for three years, which shows typical bronzing of the skin and great muscular weakness.

Gastro-intestinal symptoms were pronounced and there was complete absence of HCl in the stomach. Under prolonged dietetic treatment and lavage, with the administration of HCl by mouth, the patient has gradually improved until now he is almost of normal weight, and the bronzing and pigment patches in the mouth have almost disappeared. Severe gastro-intestinal disorders are a very common accompaniment of Addison's disease and, as in certain types of pernicious anemia, they probably play an etiological rôle. The pigment formation in Vagabond's Disease is not due solely to the parasites, but to the bad condition of the nutrition as well. It is also certain that there can be quite extensive disease of the suprarenal glands without pigmentation of the skin. It is probable that in certain of these cases, toxins arising in the intestine exert a harmful influence on the "chromaffin" tissue of the body, thereby causing bronzing and cachexia. When these toxins are eliminated the chromaffin system is given a chance to regenerate and a cure of the disease may take place.

6. Einhorn has simplified the Adler blood test. He prepared an aloin paper and a benzidin paper. Aloin paper was made by saturating ordinary filter paper with a solution of aloin in 70% alcohol; the benzidin paper by moistening filter paper with a saturated solution of benzidin and glacial acetic acid and drying it. In preparing the paper as well as making the test, it is of importance to avoid contact with the fingers. It is best to use an ivory tipped forceps, or protect the hand by means of a towel. A piece of benzidin paper is immersed in the solution to be examined and a few drops of hydrogen peroxide are added. The paper is placed on a piece of white porcelain and is examined for the development of a blue color. In the presence of blood a green or blue color arises in a few seconds or a minute. Regarding the sensitiveness of the reaction, it is greater if we allow more time for its occurrence. In dilutions of 1 part blood to 500 parts water a distinct reaction occurs in from thirty to sixty seconds. In dilutions of 1 to 2,000 a trace of blue occurs one to two minutes later. To wait longer for the reaction does not seem advisable, as after thirteen minutes the benzidin paper with hydrogen peroxide alone will yield a blue color. For practical purposes it will be best to wait but one minute for the occurrence of the reaction. In examining for blood in stomach contents too great a sensitiveness is not important, but rather a certainty that the test will indicate only blood. The longer we wait for the reaction the more substances besides blood may cause it. Benzidin paper may be used for testing for blood in stomach contents, urine and feces.

1. Ehrhardt reports four cases of progressive skin phlegmon due to diphtheria bacillus. The condition occurred in weak, badly nourished children, having a poor resistance. The point of entry of the bacillus was always a small excoriation and the infection showed none of the characteristics of wound diphtheria. It descends to the deeper layers of the cutis and subcutis and spreads out into the surrounding tissue by means of the lymph channels. In some cases the patient had a coexistent diphtheritic process in the throat, in others none was demonstrable. The infection sets in with symptoms of a sharp febrile attack; locally, an infiltration of the subcutaneous tissue is seen, which rapidly spreads, the skin soon becoming loosed from the subcutaneous fascia, is bright red, injected, soft and edematous. Palpation reveals a hard infiltration in the deeper structures. Frank abscesses never occur. The pus is always thin and watery. On incision the skin is seen to be raised from the subcutaneous tissues, with pocket formation between the fascia and subcutis. This undermining of the skin goes forward rapidly, but has no tendency to burrow deeper. Widespread gangrene of the skin soon develops. The diagnosis is made by isolating the diphtheria bacillus from the pus, either by cover glass preparation or culture. The general appearance at first is that of a severe erysipelas. The prognosis is bad. Recovery is slow and healing results in extensive scar formation. The treatment should be antidiphtheritic combined with wide incisions and draining.

5. During the last ten years the gastric juice of pig and dog have been tried in the treatment of certain diseases of the stomach, for these animal gastric secretions are known to contain a very high percentage of free HCl. Rosenberg points out that the same result may be obtained by using the gastric juice of patients suffering from continuous or intermittent gastric hypersecretion. The gastric juice of such patients contains as a rule a much higher percentage of acid than normal, and in certain cases had an acidity equal to that of the dog. In a series of eight cases of hypoacidity from different causes, the author used the filtered gastric secretion from a patient with Reichmann's disease, in whom no trace of syphilis or tuberculosis could be found. This gastric juice had an average HCl content of 90, a high proteolytic power, and a pepsin content of 3.8. One teaspoonful of this was given four times a day, before food, during a period of six weeks. Weekly examinations of stomach contents showed no change in motility or digestive power, and no increase in the amount of free HCl. The filtrates showed no increase in intensity of the Biuret reaction. A few of the patients regained their appetites, a few gained weight, a few found their gastric distress bettered. The author points out that even with this gastric juice having so high an acid content, not enough can be given to really affect the acidification of proteids in the stomach and concludes that human gastric juice, as well as animal, is no more than a good stomachic, and in no way more valuable therapeutically than the old HCl treatment.

1. Rovsing, in a very interesting paper, reports his experience in fifty-six cases of tubercular infection of the bladder. Fifty-six and four-tenths per cent of the cases of renal tuberculosis he finds complicated by a like infection of the bladder. Thus the infection is usually primary in one or both kidneys, exceptionally primary in the genital tract and very rarely primary in the bladder itself. It is hopeless to attempt to heal a tubercular bladder in the presence of the primary focus. The condition of the kidneys must be carefully studied by means of ureteral catheterization and bacteriological examination of the urine. If on catheterization turbid urine is collected from each side it does not necessarily follow that both kidneys are tubercular, for cases of the author have shown that tuberculosis from the bladder can ascend a healthy ureter. In such cases, as also in those cases where catheterization cannot be accomplished because of ulcerations, strictures, etc., an explorative incision in each lumbar region, with ureterostomy will give evidence for correct future treatment. After excision of the kidney primarily affected, it is not rare to see a beginning bladder tuberculosis heal spontaneously. If this does not occur, Rovsing injects a 6% solution of carbolic acid. The pain of such an injection may be combated by previous instillation of a 2% cocaine solution. This treatment, persisted in for from one to six months, has resulted in cure in thirteen of the author's cases.

2. Only 3 cases out of a total of 4,313 treated in Körte's clinic at Berlin developed tetanus during the years from 1890 to 1905. Busch, therefore, concludes that prophylactic injections of anti-tetanic serum are not advisable in that community, for the ordinary sort of wounds. He advises its employment, however, in cases of gangrene from frostbites, wounds by firearms, or when the wound has become contaminated by street dirt or garden soil.

3. Röpke reports two cases of bone formation in the abdominal muscles, the one five months, the other a year, after laparotomy. Neither wound was drained. After reviewing cases from the literature, and calling attention to the experiments of Liek, which demonstrated bone formation in the rabbit's kidney following ligation of its vessels, Röpke advances the following explanation for the occurrence of bone in muscle after trauma: such deposits are usually found near the muscular insertion and occur in cases where the trauma has been so severe that there ensues marked necrosis. The damaged tissue, in such close proximity to bone, quickly absorbs lime, whereby the new connective tissue becomes ossified.

4. Wolf calls attention to the absolute uselessness of injections of thiosinamin when used in an attempt to remove scar tissue in internal organs. Its use is not without danger, for if there be any latent focus of an inflammatory nature anywhere in the body, this is very apt to be made worse. He feels that the drug may be of value in the treatment of keloid or Dupuytren's contracture, if combined with massage, passive motion, etc. [Observations of its action on three cases of keloid made by Dr. M. Boehm and Dr. Quinby at the Massachusetts General Hospital in the winter of 1905 proved the uselessness of the drug, even in superficial scars.]

5. Pincus reports eighteen cases of tumors occurring in the naso-pharynx at v. Bergmann's clinic. The various operative procedures adopted are given in detail.

10. Wedensky calls attention to the part played by the external and internal vastus and the tensor of the fascia lata in aiding extension at the knee-joint. Their action becomes of especial importance when the patella has become broken or its ligament ruptured. [W. C. Q.]

Miscellany.

A CANCER EXHIBITION.

In connection with the general meeting of the International Surgical Society in Brussels, in September, 1908, at which a discussion on cancer will take place, it is proposed to arrange a cancer exhibition, and a circular has been issued inviting contributions, not only from members of the society, but also from others. All objects connected with cancerous disease will be received, but the following classes are enumerated: (1) Macroscopic or microscopic specimens, either instructive from a surgical standpoint or of special interest on account of their localization or method of dissemination; (2) topographical anatomical specimens or drawings illustrating individual operations for cancer; (3) topographical anatomical preparations of the lymphatic vessels and glands of particular regions; (4) statistical wall charts illustrating the duration of the treatment of cancerous diseases; (5) statistical wall charts illustrating the frequency of primary cancer and its metastases in particular organs, based upon clinical or pathological experience; (6) statistical charts dealing with the spread of cancer in different countries, exact plans of so-called cancer foci, and family trees of families in which cancer has existed for several generations; plans of cancer institutions and hospitals, their reports of work done, and financial statements; (8) reports of movements to encourage the early treatment of cancerous diseases, appeals to the public, and proposals as to the means by which a knowledge of the importance of the early diagnosis of cancer may be brought home to the public without exciting panic. Communications should be addressed to Prof. A. Depage, 75 Avenue Louise, Brussels, who will take charge of the specimens, arrange them for exhibition, and return them at the close of the meeting. Exhibitors will have an opportunity of demonstrating their specimens to members during the meeting. — *British Medical Journal.*

Correspondence.

HEMORRHAGIC INFARCT OF THE INTESTNE.

BOSTON, Sept. 10, 1907.

Mr. Editor: Kindly permit me to call your attention to an editorial which appeared in the JOURNAL of Aug. 29, entitled "Hemorrhagic Infarct of the Intestine." From statements there made one is led to conclusions in regard to the condition which I am sure are erroneous. The subject is a much larger and more complicated one than the writer seems to recognize. For instance, he makes no account of infarcts due to arterial embolism, but speaks only of those due to venous thrombosis. He does not mention that, though diarrhea is the rule, about a fifth of the cases show obstipation. One is led to expect the presence of a palpable tumor, when in reality this is quite rare. The diagnosis is *not* easy; on the contrary, all writers admit it to be exceedingly difficult. At operation, end-to-end suture should *never* be employed; the second method mentioned by the writer, that of sewing the cut ends of the gut into the wound, being the only safe procedure. Up to 1904 there had been 5 complete cures by operation, so undoubtedly at the present date the number is still larger. Finally, though the condition is rare, it certainly cannot be said to be "most infrequent." These remarks are based on an analysis of 214 cases made in 1904 which appeared under the title of "Mesenteric Embolism and Thrombosis," Jackson, Porter, Quinby, in the *Journal of the American Medical Association* for that year.

Very truly yours,

WM. C. QUINBY.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING SEPT. 7, 1907.

E. J. GROW, surgeon. Detached from duty at the Naval Hospital, Washington, D. C., and ordered to the Bureau of Medicine and Surgery, Navy Department.

W. G. FARWELL, medical director, retired. Detached from duty at the Navy Recruiting Station, Philadelphia, Penn., and ordered home.

H. BUTTS, assistant surgeon. Detached from the "Maryland" and ordered to the Naval Station, Cavite, P. I.

T. H. STREETS, medical director. Ordered to additional duty as a member of the Naval Retiring Board, Washington, D. C.

W. A. MCCLURG, medical director. Detached from the Marine Barracks, Washington, D. C., and ordered to duty as president of the Naval Examining and Medical Examining Boards, Washington, D. C.

C. D. LANGHORNE, surgeon. Detached from the Navy Yard, Washington, D. C., and ordered to the Marine Barracks, Washington, D. C.

C. J. DECKER, surgeon. Having been examined by a retiring board and found incapacitated for active service on account of disability incident thereto, is retired from active service from Aug. 31, 1907, under the provisions of Section 1453, Revised Statutes.

C. G. ALDERMAN, assistant surgeon. Detached from the Naval Hospital, Puget Sound, Wash., Sept. 15, and ordered to the Naval Medical School, Washington, D. C., Oct. 1, for instruction.

F. X. KOLTES, assistant surgeon. Detached from the Naval Hospital, Mare Island, Cal., Sept. 15, and ordered to the Naval Medical School, Washington, D. C., Oct. 1, for instruction.

EXAMINATION.

ANATOMIST (MALE). ARMY MEDICAL MUSEUM.—The United States Civil Service Commission announces an examination on Oct. 23, 24, 1907, to secure eligibles from which to make certification to fill a vacancy in the position of anatomist (male), at $1,600 per annum, in the Army Medical Museum, office of the surgeon-general, and other similar vacancies as they may occur there.

Applicants should at once apply either to the United States Civil Service Commission, Washington, D. C., or to the secretary of the board of examiners for application Form 1312. No application will be accepted unless properly executed, including the medical certificate, and filed with the Commission at Washington. In applying for this examination the exact title as given at the head of this announcement should be used in the application.

RECENT DEATHS.

DR. GAYLORD PARSONS CLARK, dean of the faculty of the College of Medicine, Syracuse University, died suddenly from cardiac disease at his home in Syracuse, N. Y., on Sept. 1. He was fifty years of age, and was graduated from the medical school in which he held office, in 1880.

DR. LANSING B. WINNE, a well-known physician of Albany, N. Y., who is stated to have been suffering from mental trouble for some time past, committed suicide on Sept. 2. His body was found several hours after death in the chapel adjoining Holy Innocents Episcopal Church, of which Dr. Winne was a vestryman. There was a bullet wound over the right temple, and a revolver was in his hand.

Original Articles.

A SUPPURATING SUPERNUMERARY URETER OPENING INTO THE PROSTATIC URETHRA.

BY ARTHUR L. CHUTE, M.D., BOSTON.

THE following case illustrates a rare anomaly of the ureter, of which I have been able to find few similar instances.

The patient, a man of forty-two, was first seen at the Boston Dispensary in the fall of 1905 in the service of my colleague, Dr. C. M. Whitney. His history was that of a urethral discharge that was followed by an epididymitis eleven years before. Since this urethritis he had had a great deal of backache, as well as suprapubic pain and pain in his groins and perineum. He noted in 1900 that his urine was turbid and thinks that it may have been even before this time. Since 1900 he had had to get up three or four times at night, but micturition had been practically painless. He had had bladder irrigations for some two years and also had been treated for vesiculitis and prostatitis, but without effect.

Examination showed a very turbid urine containing pus, small round cells and bacteria in abundance. Neither kidney was palpable nor tender. His prostate, vesicles and testes were normal. Cystoscopy showed a bladder that was unusually tolerant, allowing easily a distention of from 12 to 16 oz. There was a slight cystitis of the lower part of the bladder and a puckering high up on the posterior wall that I supposed was due to a former ulceration. The right ureter was normal and emitted very frequent jets of what appeared to be clear urine. The left ureter was "slipper" shaped with the bladder moderately distended, while with a fully distended bladder it gaped widely and a little turbid fluid could be seen issuing from it at irregular intervals. A catheter passed into the left ureter gave very little urine, but when passed to the kidney pelvis it evacuated 2 oz. of turbid fluid in a short time. This fluid contained a trace of albumin, 0.50% urea, blood, pus, round cells and bacteria. Neither slide preparations nor a guinea pig inoculation showed tubercle bacilli. A specimen from the right kidney showed a very actively secreting organ. The urine was transparent; it contained a very slight trace of albumin, and 2.27% of urea. The sediment which was very slight showed a single cast, some epithelial cells and a little normal blood, the last probably due to slight injury by the catheter.

Several examinations gave practically this same result. Washing out his left kidney pelvis would lessen for a time the turbidity of his urine and his frequency of micturition but gave only temporary relief. He was advised that drainage of his left kidney, or possibly its removal, was the only thing that would permanently benefit him. He was unwilling to undergo operation and ceased to attend the clinic.[1]

After an absence of eight months, this man reappeared in August, 1906, with the story that up to a few weeks before he had been as when last seen. For a few weeks he had been having frequent and painful micturition, he had lost appetite and weight and had had occasional chills. His urine was turbid, of an orange color and with a peculiarly offensive odor. On standing in a cylindrical glass it deposited a sediment that was nearly one half the height of the column of urine. This sediment showed pus, epithelium, a little blood, and immense numbers of a staphylococcus of some sort. The kidneys could not be felt; there was no tenderness in either loin. There was pain to the left of the bladder and just behind it and there was tenderness at these points, as well as over the lower part of the left ureter. His bladder washed clean very easily but was less tolerant than formerly. The ureters were as at the previous examination, but the lower part of the bladder showed a greater degree of cystitis. Behind and to the outside of the left ureter there was a localized patch of cystitis as there was also on the posterior wall rather nearer the left than the right side. At these points the mucous membrane was very dark red and thrown into folds, which in some places were surmounted and in others bordered by reddish vesicles.

Catheter specimens were taken from the lower part of both ureters. That from the right now contained a good many casts, some with blood and epithelial cells adherent. Stained specimens of the sediment, however, gave no bacteria, showing that the condition was toxic rather than infectious. The urine from the left ureter was very small in amount and was as at the previous examination.

When after the cystoscopy this patient came to empty his bladder it was noticed that the fluid was followed by several drops of pure pus, and that by straining with his bladder empty he could express pus in little jets. Pressure behind and to the left of the bladder increased the amount of pus he could express. His prostate was neither tender nor enlarged. It was found that he was running an evening temperature of from 101° to 103°.

On several occasions a large catheter was placed in his bladder and during the time it was in position the bladder urine contained much less pus. After leaving the catheter in place for a few hours his pain would increase and his temperature go up. On removing the catheter an unusual amount of pus would be discharged with relief to his pain. This and the area of edema bullosum led me to believe that he had a collection of pus behind and to the left of his bladder that connected with the prostatic urethra either through the prostate or a seminal duct. The fact that with the catheter in place the bladder urine was much less turbid, made it seem probable that the left kidney was not, at least, the immediate cause of his acute symptoms.

A perineal section that I did early in September, 1906, showed a point on the left lateral wall of the prostatic urethra, about half an inch in front of the bladder sphincter, from which pus was oozing and from which more could be forced by pressure above the bladder. This opening was dilated, a tube inserted, and a catheter fixed in the bladder. Drainage from the tube was free and his temperature came down, but not to normal. As the perineal wound closed the temperature went up again and there was a tenderness over the whole course of the left ureter and left kidney, though no distinct mass could be felt.

At a second operation, some weeks after the first, a left-sided extra-peritoneal incision was made in order to explore the lower portion of the ureter and the region behind and to the left of the bladder. A normal looking ureter was found in its usual position; this was followed to the bladder and showed no abnormality. The region to the left of the bladder showed nothing more than brittle, friable fat, that had evidently suffered inflammatory attacks. Behind the bladder, to the inside of the normal ureter, and very closely bound to it by adhesions at the point where the normal ureter joined the bladder, there was a thick walled tube which

[1] The history of the case to this point has been reported as an illustration of the fact that a renal suppuration does not necessarily give symptoms distinctly referable to the kidney; that it may in fact point more to bladder involvement. Also as an illustration of the fact that palpation may not reveal a tender or enlarged kidney in some suppurations of the renal pelvis. "Some Cases Illustrating Cystoscopic Diagnosis." BOST. MED. AND SURG. JOUR., 1906, vol. 154, p. 309, Case IV.

was nearly the size and appearance of a bit of small intestine that was without a peritoneal coat. This tube extended to the right along the back of the bladder a short distance, then becoming much convoluted it rose out of the pelvis and extended upward parallel to the normal ureter and to the inside of it. It was found to lose itself above in a big flabby sac, evidently a dilated kidney pelvis. After freeing this tube it was tapped and found to contain very foul pus. The patient's condition was too poor to allow of a nephrectomy or kidney resection, so the abnormal ureter was cut close behind the bladder and a large drainage tube sewed into its stump. After removing a section of the tortuous ureter, and passing a tube through it into the dilated kidney pelvis, its upper end was brought out at

the superior angle of the incision and fixed to the skin. Nothing was done with the normal ureter. The muscles and skin were sutured between the two tubes.

There was for several days after operation a moderate sepsis due to soiling of the denuded surfaces during operation. The wound did not, however, break down at any point, and after a few days the temperature reached normal. The dilated kidney pelvis did not drain satisfactorily and had to be irrigated. At first it would hold 4 oz. of fluid without giving discomfort, later it contracted a little. There was at no time any discharge from this ureter that in the least resembled urine. Before the tube that had been sewed into the lower end of the abnormal ureter was removed it was found that fluid syringed into it escaped into the urethra.

When convalescent, this patient's bladder was again examined and it was found that the two areas of localized cystitis with edema bullosum had entirely cleared up. The ureters were catheterized simultaneously — the right discharged rhythmically an abundance of normal looking urine, while the left gave at first a continuous drop-by-drop stream of suspiciously pale fluid that later came rhythmically. As I suspected from the color of the fluid that the left ureter was dilated and was allowing fluid from the bladder to flow up the ureter, and that the rhythmical discharge was really due to bladder contractions, I injected methylene blue into the bladder through a third catheter. The blue made its appearance in the left catheter at once.

The left kidney was removed through a lumbar incision four weeks after the second operation. It was adherent everywhere and had an artery entering both the upper and the lower pole. The ureter that emptied into the bladder arose from the lower pole and was cut a few inches below the kidney. The pyo-ureter was dissected out with a small margin where it had adhered to the skin. The wound was closed in layers with drainage. The patient's convalescence was interrupted on the fifth day by an attack that seemed like a thrombosis somewhere in his left loin. It was attended with great pain, rapid pulse and respiration and diminished excretion of urine; other than this temporary upset his convalescence was normal and he left the hospital about the middle of December with all his wounds solidly healed and passing a nearly transparent urine, the first portion of which contained a few shreds presumably from the stump of the abnormal ureter.

The kidney prepared for me by Dr. Leary, showed on section two pelves that did not communicate with each other. The upper pelvis, the one drained by the pyo-ureter, was much larger than the one that connected with the bladder. It would hold about 4 oz. of fluid. There was no vestige of secreting tissue but there were several depressions, evidently the remains of calices. There was an apron or septum that partly occluded the opening of the pelvis into the ureter, while the ureter just below the pelvis showed an "S" shaped curve that was not unlike a plumber's trap. The walls of the ureter were much thickened. The appearance of the cavity was not that of a congenital cyst but more that of a kidney whose secreting tissue had been completely destroyed by suppuration. That portion of the kidney that emptied into the bladder was limited to the lower pole and was much the smaller of the two. There was at one point a little crescent of what looked like secreting tissue but with this exception there was no suggestion of renal substance. There were several depressions in the lesser pelvis that were probably the remains of dilated calices. Though at my first examination I had gotten 2 oz. of residual urine from this pelvis, it had contracted so that it would hold only about 1 oz. There were two renal arteries that entered, one near either pole.

The examination left no question but that we had to do with a congenitally malformed kidney having two pelves and ureters. The appearance of the larger cavity indicated that most of the secreting tissue had opened into it. The ureter from this section of the kindey, through a fault of development, opened into the prostatic urethra instead of into the bladder. Its lower end was apparently surrounded by prostatic tissue.

Whether the infection was an ascending one, due in the first instance to a gonorrheal urethritis, as seems most probable, or whether it was descending, due to a hematogenous infection of a badly drained kidney

pelvis, is something concerning which one can only speculate. Everything pointed to the probability that the infection had been present for a very considerable time and that the onset of the more acute symptoms early in the summer did not by any means mark the beginning of the process. The true nature of the condition was not recognized until the time of the second operation.

This case presents in reality two abnormalities: that of a double ureter, and that of an abnormal opening of the lower end of a ureter. Though these two deformities were combined in this instance, and are in a large proportion of such cases, they are not necessarily so; there are numerous instances of double ureters entering the bladder in a practically normal manner as well as instances where the lower end of a single ureter has opened abnormally. Of 9 cases of ureters opening into the prostatic urethra collected by Schwarz, duplication was present in 7, while in 2 the ureter was a single one.

Unilateral duplication of the ureter is a fairly common anomaly, the frequency of which has been variously estimated by different writers; thus Lessing places it at from 1% to 4%; Zondek at 3% to 4%, and Robinson at about 4%. The duplication is due to the fact that the Wolffian duct gives off at an early stage of intra-uterine life two ureteral buds instead of one, both of which develop into a ureter usually connected with its own separate renal pelvis. When double ureters enter the bladder approximately normally as they may often do, they give rise to no symptoms. This was the case in a patient whom I recently cystoscoped for another condition and on whose right side I found two ureteric openings, from which swirls of urine could be plainly seen. With rare exceptions duplication of the ureter is of clinical interest only when one or both ureters show an opening that is abnormal, either as to its caliber or its location.

An abnormal opening of the lower end of the ureter is rarer than mere duplication and of more surgical interest. Certain types, such for instance as where a ureter opens into the vagina, occur not very infrequently and invariably give rise to very annoying symptoms demanding surgical treatment. Other types, such as that seen in the reported case, are much rarer and demand surgical treatment less frequently.

The various types of abnormal ending of the ureter depend upon developmental errors. In some this error is relatively slight, as for instance when a ureter enters the bladder by an abnormally small orifice, or when it ends in a cystic dilatation just under the mucous membrane of the bladder. These are instances where there has been a relatively slight arrest in development, a failure either to perforate the bladder membrane or to make a sufficiently large opening. Cases of this type, though they represent a relatively slight developmental error may give rise to serious trouble as is evident from a perusal of the cases of this sort collected in the papers of Grosglik and Cohn.

The more marked abnormalities of the lower end of the ureter, particularly those that are attended with a considerable change in its location, are brought about in the very complicated shifting that takes place at the time that the Wolffian duct and the developing ureter cease to enter the allantois by a common opening. At this time the Wolffian duct, and the non-developed Müllerian duct in the male, separate from the urinary tract and go to form the seminal tract. During this change the Wolffian duct closes its original opening into the allantois, while the ureter prolongs downward its original lateral opening into the Wolffian duct, until it opens into the bladder. Certain abnormalities, such as the opening of a ureter into a seminal vesicle or any part of the seminal tract are due to a failure on the part of the developing ureter to separate from the Wolffian duct, while that organ, after closing its opening into the fetal bladder goes on with its normal plan of development. Other changes are apparently

due to a displacement of the lower end of the developing ureter, that seems best explained by a pulling or crowding of the ureter of the embryo by the Wolffian duct, which is very active at this time and changes its position very materially. A relatively small displacement of the ureter at this early stage of intra-uterine life may result in a considerable deviation from the normal at full term. A slight displacement forward suffices to bring the fetal ureter into contact with the tissues that are to form the deep urethra, and this probably accounts for anomalies of the type seen in the reported case. The instances where a ureter opens into the urethra in women are probably brought about in the same way. In the cases where a ureter courses through the prostate it is probable that the ureter does not pierce, so to speak, the developing prostate, but that the prostate which is an outgrowth from the deep urethra develops about the already abnormally placed ureter. It is improbable that abnormal ureters that open

into the prostatic urethra *at the veru montanum* take their origin from an abnormal connection between the ureter and a Müllerian duct.

While the lesser abnormalities of the lower end of the ureter, such, for instance, as an abnormally small opening into the bladder, or a cystic ending under its mucous membrane, are due to slight arrests in development, the more marked changes in the location of the ureteric orifice must, in the male at least, be attributed to the disturbing influences which the Wolffian duct, under certain unknown conditions, exerts upon its off-shoot, the developing ureter. In the female we have to take into account beside the distortions due to the Wolffian duct, which would account for ureters opening into the urethra, the influence of the Müllerian duct. An abnormal communication between this organ and the ureter probably accounts for ureters that open into the vagina. The explanation of the exact mechanism by which some of these changes take place is at present quite impossible since the whole subject is too imperfectly understood.

A study of the recorded cases of the particular type of the one reported brings out several points of interest, both as regards double ureters and ureters opening into the prostatic urethra. In instances where there are two ureteral openings there will almost invariably be two non-communicating pelves, each with its own area of secreting tissue and often with its separate afferent blood supply as well. The ureter with the lower and more external opening will almost, without exception, lead from the upper pelvis. This has been called Weigert's rule and may be of use in planning a kidney resection should it be indicated.

When a ureter opens into the prostatic urethra there is no incontinence of urine. So long as the ureter remains uninfected there will usually be no symptoms. The rarity with which ureters opening into the prostatic urethra have been noted is probably in part explained by the fact that such cases unless infected are symptomless and are therefore unrecognized. The history of the reported case, as well as some others, makes it evident that in cases when a ureter opens into the prostatic urethra, the urethra gets accustomed to the presence of urine and allows it to pour back into the bladder without causing the reflex desire to empty the bladder that is supposed to take its origin from the entrance of a few drops of urine into the prostatic urethra. Meslay has suggested that a ureter opening into the prostatic urethra will be particularly liable to become infected at the time of puberty, due to the fact that the enlargement of the prostate that takes place at that time will have a tendency to press upon the ureter and interfere with its emptying itself.

As symptoms arise only in cases where there is infection, and as infection of a badly drained ureter speedily gives rise to a renal involvement, the signs will in general be those of a kidney infection. If on cystoscopic examination no ureteric orifice was found on the side giving evidence of kidney involvement this would be suggestive. This could occur only in cases where there was no duplication of the ureter. A sign that would be more suggestive of a renal suppuration of this origin is the ability to force out little jets of pus or turbid urine, immediately after the bladder has been completely emptied by a catheter. This in itself would not distinguish the condition from any other collection of pus opening into the deep urethra, but with other collections of pus a mass or induration would be found, which is not the case in this condition. Though in the reported case the ureter passed through the substance of the prostate, repeated rectal examinations failed to show any mass or tenderness. In most cases a definite diagnosis will not be made before the kidney or course of the ureters has been exposed.

Since attention will rarely be called to this condition until infection has taken place, the treatment of these cases in which a ureter opens in the prostatic urethra, will be nephrectomy in perhaps most instances, whether the kidney has one ureter or two. In some cases presenting a duplication of the ureter, resection of the diseased part of the kidney and the diseased ureter may be possible, as was done in a case reported by Albarran. One can conceive of cases in which the disease process had not extended so far, but that it might be possible to transplant the lower end of the ureter into the bladder and by draining the kidney preserve some secreting tissue. This would be particularly desirable to try in cases in which an only ureter opened into the prostatic urethra, or where the kidney of the other side was somewhat damaged.

A review of the literature of this subject warrants one in considering this condition a rare one. If one takes into account the cases in which a ureter has opened into the urethra in women, which are probably due to an analogous developmental error, the number of reported cases would be considerably increased. Schwarz in his article written in 1896 brought the general subject of abnormal endings of the lower end of the ureter down to that time. He collected from the literature but nine instances in which a ureter had opened into the prostatic urethra. All of his cases were autopsy reports. While I have in all probability overlooked some instances I have found recorded since the date of Schwarz's article but 4 additional cases. Of these 4, but 1 case, that of Albarran, was operated upon.

A synopsis of these cases follows.

Meslay. — A man who died of a cerebral lesion presented bilateral duplication of the ureter. The supernumerary ureter on the left opened into the prostatic urethra; that on the right ended in the prostate itself. Though it was known that this man's urine had been turbid for some months before death, his parents were unaware that he had complained of any urinary trouble.

Obici. — The autopsy of a man of fifty-five who died of pneumonia showed two ureters on his right, both of which traversed the muscular wall of the bladder just under the mucous membrane and opened "some millimeters from the neck." The context implies that the ureters opened into the

prostatic urethra since it was stated that there was no incontinence. No other symptoms were given.

Nicolich. — In 1904 Nicolich demonstrated before the French Urological Association a specimen taken at autopsy from a man of forty, who died of pneumonia. There was no account of his urinary symptoms. On the right there was what Nicolich took to be a persistent Müllerian duct. Below it opened by a small orifice into the prostatic urethra; above it ended in a "sac superimposed on the superior pole of the kidney."

After examining the specimen Albarran expressed the opinion that it was really a double kidney, one ureter of which opened into the prostatic urethra.

Albarran.— Before the same meeting and as analogous to the above case reported by Nicolich, Albarran described the case of a young man of twenty-six, who came to him with a fistula that had followed a nephrotomy done for a pyonephrosis. At the operation to close the fistula, Albarran found what he termed "two kidneys separated only by a furrow." The upper one he resected with a considerable length of its ureter. He assumed that this ureter opened into the prostatic urethra, though he was unable to demonstrate this fact. He had, however, been able to demonstrate by cystoscopy that the ureter did not open into the bladder. It may be assuming too much to include this case with the others.

The condition is undoubtedly a rare one, but probably not so rare as one would be led to suppose from the literature. It should be considered as a possibility when one is dealing with atypical urinary suppurations.

I am indebted to Mr. Walter Manton for the cuts that accompany this article.

RECENT ADVANCES IN THE KNOWLEDGE OF TUBERCULOSIS IN EARLY LIFE.*

BY CHARLES HUNTER DUNN, M.D., BOSTON,
Assistant in Pediatrics, Harvard Medical School; Assistant Physician at the Children's Hospital, and at the Infants' Hospital, Boston.

THE literature produced in the last few years on the subject of tuberculosis in early life is so enormous and the number of new observations, experiments, facts and theories contained therein so great, that it is exceedingly difficult to summarize the recent advances in the knowledge of this disease. Moreover, the views brought forward are so divergent, yet are all supported by such masses of carefully obtained and compiled evidence, that it is still more difficult to choose among them, or to form any satisfactory conclusions. The subject is still under discussion, and is now more than ever full of open questions, to which the final answers must still be awaited.

In this paper I shall endeavor to summarize some of the results of all this work. I shall present as facts those points which are admittedly established, and shall give my personal opinion on the preponderance of the evidence in the points under discussion, in which an exhaustive study of the literature has enabled me to form an opinion. The remaining points will be presented as theories, or as open questions.

INCIDENCE OF TUBERCULOSIS IN EARLY LIFE.

Important conclusions, based on an immense number of autopsies, have been drawn as to the frequency of tuberculosis in early life. It has for some time been known that this disease is exceedingly common in childhood, more so than has been generally supposed. But the most striking fact brought out in the autopsy statistics is that the frequency of occurrence of tuberculosis increases regularly with the age. It is rare in the first three months of life, and increases steadily throughout childhood, not only from year to year, but also, in the first two years, from month to month. According to the statistics of various observers, it is as follows:

First three months,	0– 2%
Second three months,	16–17%
Second six months,	22–26%
1–2 years,	42–44%
2–10 years,	67%
10–15 years,	64–77%

This fact is of great significance in connection with the question of source and mode of infection, to be discussed later.

The same statistics show that tuberculosis as the cause of death in those cases in which it was found at autopsy decreased with advancing age. Hamburger and Slicka, whose figures are based on 2,557 autopsies on children under fifteen years, found that in all these cases in which tuberculosis was found in children under six months, it was the direct cause of death, but that in children, in the second six months, it was the direct cause in 75%. Over two years, it is much more infrequently the direct cause of death.

They also found absolutely no evidence of any tendency toward healing in the first two years of life.

It should be mentioned here that Salge concludes from careful researches that autopsy findings are not an absolute indication of the prevalence of tuberculosis in early life, but represent only a minimum, as virulent bacilli may be present without producing demonstrable lesions.

* Read in the Section of Tuberculosis in Children, of the National Association for the Study and Prevention of Tuberculosis, at the Third Annual Meeting, Washington, D. C., May, 1907.

NATURE OF THE TUBERCULAR PROCESS IN EARLY LIFE.

Recent studies also have emphasized the great difference in the pathology of tuberculosis in early life from that of adult life. Tuberculosis in infancy and childhood is essentially a disease of the lymph nodes. Tubercular adenitis represents the chronic tuberculosis of childhood, as phthisis represents the chronic tuberculosis of the adult. The autopsy statistics quoted above showed tubercular involvement of the bronchial lymph nodes in 98%; the mesenteric lymph nodes in 36%; the cervical lymph nodes in 30%.

Leaving aside for the present the questions of the source of the tubercular infection, and its point of entrance into the body, we know that in children the bacilli do not usually cause demonstrable primary lesions of the skin or mucous membranes, but localize themselves in the lymph nodes. Here they set up a chronic process, which authorities agree to be a reaction of defence, directed toward the prevention of a further extension of the virus. In proportion to the completeness of this protective reaction, the bacilli are either prevented from multiplying, and thus may remain indefinitely latent, or they multiply, though prevented from spreading. In the former case, there are no clinical manifestations; in the latter, there are faulty nutrition, loss of weight, and occasionally fever.

There is at times a further extension of chronic tuberculosis. This occurs when virulent bacilli, escaping into the circulation, localize themselves in such a tissue that the tissue reaction again succeeds in limiting their further spread. This is, in fact, a true metastasis. Examples are, the tuberculosis of the bones, and the solitary tubercles sometimes found in the brain or liver.

This metastasis of chronic tuberculosis is, however, not the usual method in which further spreading takes place. The usual method is the acute tuberculosis of early life. When the resistance of the human organism is lowered by some cause, such as an intercurrent infection, notable among which are measles, and pertussis, or some indeterminable cause, the bacilli invade the general circulation and produce an acute general or localized miliary tuberculosis. It was formerly supposed that miliary tuberculosis occurred only when a large number of bacilli suddenly escaped into the blood stream. The weight of modern opinion does not believe this, but rather that a few, possibly only one, escape, the main point being that a vascular lesion is formed, from which as a nidus further extension occurs. Thus, for example, in tubercular meningitis one bacillus may cause a tubercle in the lymph spaces of the pia, from which as a source the infection spreads along the course of the vessels, through the vascular channels throughout the tissue. General miliary tuberculosis is due to a tubercular vascular thrombus, which forms a similar nidus.

Although tubercular meningitis and acute miliary tuberculosis are the commonest acute manifestations of tuberculosis in early life, and are responsible for the greater part of the mortality, other acute or subacute forms occur, such as tubercular bronchopneumonia and tubercular peritonitis. In the latter, the infection reaches the peritoneum through the lymphatics, and a tubercle is formed which forms the nidus from which the general involvement of the membrane takes place. Whether in tubercular bronchopneumonia the invasion occurs through the pulmonary lymphatics, or from a fresh aërogenous infection, is one of the questions which still remain unsettled.

SOURCES OF INFECTION.

For a long time after Koch's discovery it was believed that tubercle bacilli, like the pyogenic cocci, were generally distributed, were everywhere, in the air, in the dust of the streets, in houses and in food. Under such circumstances every one was constantly exposed to tuberculosis, and infection occurred when resistance was sufficiently lowered to give the omnipresent germs a start. This view has been proved to be untrue. It is now generally recognized that the only source of tubercular infection is the tuberculous man or animal.

Four theories have been held as to the source of the infection. First, the congenital theory, advanced by Baumgarten, that tuberculosis is always intra-uterine in origin, due to placental infection. While there is evidence that tubercular infection can, in very rare cases, occur in this way, there is absolutely no evidence that it plays any important part. Second, that infection takes place from the inhalation of dried tubercular sputum. Cornet, who advanced this view, supported it by many ingenious inhalation experiments on animals, from which he concluded that it represented the only source of infection. The experiments are highly artificial, and the weight of modern opinion does not accept in full Cornet's conclusions, though admitting that the dust from dried sputum is in fact a source of infection of great importance, and that Cornet has conferred great benefit on the progress of study by calling attention to its dangers. The third view is that supported by Flügge, that the source of infection is the fine moist drops expelled in coughing. This also is a possible, but by no means exclusive, method of acquiring the disease. Its chief benefit was in calling attention to the danger of the tuberculous individual. The fourth view is that the source of tubercular infection is the milk of tuberculous animals. The most extreme supporter of this view is, or was, Behring, who asserted that tuberculosis is always primarily a disease of infancy, and that at whatever age and in whatever form it manifested itself clinically, it was always due to a milk infection occurring in infancy. The phthisis of adults, he said, is only the concluding chord of the infant's cradle-song. This view naturally was of intense interest to pediatrists, and aroused a controversy which has ever since been raging in the scientific journals. In its support are the results of much painstaking

study on human and bovine tubercle bacilli. We know now that the bovine type can produce tuberculosis in man. Behring based his view chiefly on the fact that his animal experiments showed that it was practically impossible to infect young animals in any way except by the food, and on the frequency of latent tuberculosis in childhood.

Against it there is much to be said. One cannot reason too closely from young animals to young babies. Also, Behring's view implies the absolute identity of human and bovine bacilli, which, though a common species, we now know to be two distinct types or races, which can be mutually recognized. The bovine type is not most commonly found at autopsy. Also, studies on tuberculosis in cattle have shown that even there infection takes place most commonly by inhalation. Finally, in Japan, where there are no cattle, and where milk is never used as an infant food, tuberculosis is just as common, in just the same forms, as in milk-drinking countries.

The whole history of tuberculosis in early life is against the idea of any one exclusive source of infection. That infected food is an important source, possibly of special significance in early life, cannot be denied. Nevertheless, autopsy statistics show that the more an infant comes in contact with his surroundings the greater the liability to tuberculosis. This fact points us to the chief factor in tubercular infection, the surroundings of the infant. While in the cradle in his earliest months, he is comparatively protected, but as he gets older, is more carried about and handled, or when he creeps on the floor, coming in contact with soiled handkerchiefs and all sorts of other objects, putting everything he finds into his mouth, or inhaling contaminated dust, then the opportunities for infection multiply. This view of house infection, of infection from surroundings, as the chief source, is now generally held by the best authorities. Even Behring has recently modified his views to include it, and there is experimental evidence in its favor, as young guinea pigs, placed in tubercular families, contract the disease.

THE PORTALS OF ENTRY FOR TUBERCULAR INFECTION.

The main difference of opinion still remains, not so much as to the source of the infection, but as to its portal of entry into the body in early life. So high an authority as Schlossmann believes that Behring's theory of tuberculosis being always acquired through the intestine in infancy is the most important step in the progress of knowledge of this disease since Koch's discovery of the bacillus. Many other authorities believe to-day that tuberculosis is practically always acquired through the intestine.

The supporters of this view now admit the importance of house contagion, in which the child carries the bacillus to its mouth. They even admit that tubercle bacilli can enter with the air stream, in which case they believe the organisms become entangled in the secretions of the nose or pharynx, and are swallowed. In any case they reach the intestine, where the lymphatic apparatus is specially adapted to their penetration. The fact that the bronchial lymph nodes are more frequently involved than the mesenteric, is explained on the ground that the latter form insufficient filters against the penetrating power of the bacilli, which consequently enter the general circulation *via* the thoracic duct, and localize themselves in the points of least resistance, which are the bronchial lymph nodes.

This view is supported mainly by the results of experiements on animals which have lymph node tuberculosis resembling that of infancy, in which the lesions of the bronchial lymph nodes are due to ingestion of the virus, it being very difficult to produce tuberculosis by inhalation. Another argument is based on the infrequency with which the lungs and larynx are affected in infancy, and that the first lesion is always vascular. Moreover, a violent reaction of the lung is caused in infancy when by inhalation even the smallest foreign bodies enter the smaller bronchioles and alveoli, but no reaction of the lymph nodes. Also, all other infections entering by inhalation involve the bronchi or alveoli, not the lymph nodes, and hence tuberculosis is obviously hematogenous or lymphogenous.

The chief argument against this view is that it is unwise to draw such important and far-reaching conclusions as to children from laboratory experiments on animals. If it is true that the tubercle bacillus can pass through the mucosa of the intestine without producing a lesion, the same is true of the mucosa of the lung, and if the lungs and larynx are infrequently affected, the same is true of the intestine. Inhalation does not imply the entrance of a number of bacilli, and hence no violent reaction is necessary. All analogy points to the lymph nodes lying nearest to the point of entrance as the ones primarily affected, which means that the more frequent point of entry is in the lungs. The behavior of dust particles is a strong argument in favor of the aërogenous origin of lymph node tuberculosis. And Theobald Smith has shown that even in cattle tuberculosis enters more often through the lung than through the intestine.

It is probable that in infancy the commonest portals of entry are the lungs, the tonsils and nasopharynx and the intestine. Corresponding with these three portals of entry, we find primary involvement of the bronchial, cervical, and mesenteric lymph nodes.

SOME THEORETICAL CONSIDERATIONS.

I must call attention to some theoretical views recently advanced by Dr. Theobald Smith. Taking up the subject of the parasitism of the tubercle bacillus from the point of view of the parasite, he points out that a stable parasitism results from a selective adaptation, the result of the interaction of two organisms. It is necessary for the continued existence of such a parasitism that the parasite shall provide itself with a mode of exit from as well as entry into the host. From

this necessity follows a lowered virulence, or invasive power, the bacillus attacks the skin or mucous membrane, and phthisis is the commonest form. Other forms, as lymph node tuberculosis, are aberrant, as the parasite must die without exit. Such forms are commoner in childhood, because the bacillus, being keyed, as it were, to adult life, is more invasive in childhood.

As a result of the study of the peculiarities of tubercle bacilli in cultures, and of the reactions to tuberculins and vaccines, Smith has formulated an interesting theory. The tissue reaction in tuberculosis is a mechanism of mutual defence on the part of the host and parasite, and is stimulated by something given off by living bacilli only. He believes the bacilli are provided with a protecting envelope, with neutral chemotaxis, which must first be removed by the body fluids, the blood, which can be compared to an opsonin, although Smith does not agree with Wright that phagocytosis and the leucocytes play much part in the defence against tuberculosis. The envelope being removed, the bacilli multiply, and stimulate cell proliferation, which checks multiplication. Some bacilli are destroyed, while the rest, protected by caseation, remain latent, provide themselves with a new protecting envelope, and, if discharged, are ready to infect again. Thus when bacilli are latent, it is because the opsonic or capsule-removing power of the blood is too low, and the body, while apparently immune, is really in a state of hypersusceptibility. When the capsule-dissolving or opsonic power rises, multiplication begins.

Without entering upon any discussion of the very technical evidence upon which this theory is based, I will say that I think it is specially attractive in connection with the peculiarities of tuberculosis in early life, namely, the great frequency of latent tuberculosis, and the frequency, extreme severity, and fatality of the acute manifestations. The child's blood is low in capsule-removing power, hence tuberculosis is latent, but the child is nevertheless hypersusceptible, hence the little resistance and slight tendency toward healing.

THE DIAGNOSIS OF TUBERCULOSIS IN EARLY LIFE.

As to the diagnosis of tuberculosis in early life, much work has been done with a view to determining the exact diagnostic value of the tuberculin reaction. It is admittedly certain in animals, but has frequently failed in adults. The conditions are believed to be more favorable in children, where the reaction is considered a very valuable diagnostic sign. Schick, basing his conclusions on exhaustive experimental work, believes that a local reaction is less apt to fail than the general constitutional reaction. He concludes that no known case where tuberculosis has been excluded with certainty has given a local reaction, and that this reaction is often the only positive sign.

As to serum diagnosis, much work has been done, but final conclusions as to its value cannot yet be drawn. Many observers believe the agglutination test to be an absolute and very early sign, while others deny its value, and have found agglutinating power in the serum of apparently healthy persons.

On the difficult subject of the clinical diagnosis of chronic tuberculosis in early life, there has been much painstaking observation, and a few new points have been brought out. D'Espine believes he has found a reliable method of diagnosticating enlargement of the bronchial lymph nodes by auscultating the voice. In a normal child the tracheal tone stops abruptly at the seventh cervical spine, but with a pathologic process in the lymph nodes it extends further downward. In the first stage auscultation on the child's crying or pronouncing the resonant words "*trois cents trois*," reveals a whispering tone superadded to the voice, which in a more advanced stage becomes bronchophony. Dullness on percussion of the seventh cervical or first dorsal spines is a later sign, as are intrascapular dullness and the bronchial souffle. Gibson has called attention to venous dilatation over the chest, neck or shoulder, tending to converge above the sternum, as a valuable sign. The most important diagnostic method, however, which we now have at our disposal, is due to the recent perfection of radioscopic diagnosis.

There has been much discussion recently as to the possibility of recovery from tubercular meningitis. In the literature of the last twelve years, I found only three cases of recovery where the diagnosis was satisfactorily established.

THE PROBLEM OF IMMUNITY.

Ever since Koch's discovery of the tubercle bacillus, for those who have busied themselves with the study of tuberculosis from the scientific standpoint, the central problem has been the conferring of artificial immunity. The problem, like most problems in immunity, is so complicated, that, as far as human beings are concerned, but little of positive and practical value has been accomplished. Nevertheless, an enormous amount of work has been done, with the result of at least clearing the ground and preparing the way for what will follow in the future.

Three methods of producing immunity have been tried. First, mithridatisation, producing active immunity by the frequent introduction of increasing doses of poison. Second, jennerisation, producing active immunity by infecting with weakened cultures. Third, serum therapy, producing passive immunity by introducing an immune serum. The third method has given no favorable results at all. The first was the method chosen by Koch, with the old tuberculin. Though useful in animals, it has failed in human beings, and it has been shown that it confers immunity only against poison, not against living bacilli. The attention of the scientific world is now focused upon the second method,—the conferring of immunity by means of vaccines.

There are many preparations of tubercle bacilli now in use as vaccines, and their value as immunizing agents is not yet settled. The question is

still in its infancy, yet some progress has been made. It has at least been determined that the immunizing power of a vaccine is distinct from its toxic action; and the most modern investigators are working with vaccine and doses which cause no general constitutional reaction.

The ingenious theory of the opsonin brought out by Wright has been applied to tuberculosis. I assume you are familiar with the general theory. As you know, he takes the opsonic index as a guiding factor in giving the tubercular vaccine. It is extremely ingenious. The chief objection is that there is no evidence that phagocytosis is at all an important factor in the protecting mechanism against tuberculosis. Granting then that the opsonic index rises after an injection of tubercular vaccine, and that a permanently raised opsonic power may be produced in the blood by repeated injections made at the proper time, nevertheless, there would be no reason to expect an increased power of resistance against the organism.

Nevertheless, other substances, true antibodies, may increase in parallel with the opsonin, which are of protective use, so that one cannot yet condemn this method. Such antibodies may be the substances which dissolve the protective envelope, as suggested by Smith.

Smith believes that the hypersusceptibility produced by an attack of tuberculosis is in reality a partial immunity, that immunity, being dependent on the tissue reaction, is of necessity focal, and though some general immunity is produced, it is not sufficient to prevent a second, a severer attack. This, though insufficient, carries with it the germ of the possibility of immunization to such a degree as to wholly prevent a second attack. The chief stumbling-block to producing immunity in tuberculosis is that the immunizing substance is toxic, and immunity requires exposure of the whole body to a toxic immunizing substance. Nevertheless, the human being is undoubtedly in a fairly good state of natural resistance toward tuberculosis, and there is much hope that a method will be devised by which by the creation of local foci under the control of the observer, general immunity may be attained.

THE REPORT OF AN UNUSUAL CASE OF ULCER OF THE STOMACH.*

BY J. M. T. FINNEY, M.D.,
Associate Professor of Surgery, Johns Hopkins University, Baltimore,
AND
JULIUS FRIEDENWALD, M.D.,
Professor of Diseases of the Stomach, College of Physicians and Surgeons, Baltimore.

The diagnosis of ulcer of the stomach is not always a simple matter. If the important symptoms of this disease are present, such as pain appearing soon after meals accompanied by nausea and vomiting, together with hematemesis and a localized painful area in the epigastrium, there is no difficulty in establishing the diagnosis; but frequently one or more of these symptoms are absent, and great difficulty may be experienced in arriving at a correct diagnosis. Leube recognized this difficulty when he advised his rest treatment in all doubtful cases of gastric ulcer in order to verify by the result of the treatment the correctness of the diagnosis; unfortunately, even this method cannot always be relied upon.

The difficulty which is sometimes met with in arriving at a correct diagnosis of ulcer is occasionally experienced, even after an abdominal incision has been made, *i. e.*, even under direct inspection of the ulcer. The case which we are about to report presents conditions of this kind.

The patient, W. H. K., age thirty-eight years, married, first presented herself for treatment on Oct. 22, 1906. Her family history was negative; her mother died of tuberculosis of the throat; with this exception her family history was good. The patient had had the diseases of childhood, including scarlet fever and diphtheria. She has complained much of shortness of breath, and during the past five or six years she has been troubled with gastric disturbances. She has had much nausea and vomiting, beginning some hours after eating. The vomited matter is very acid and contains some food remains, but never blood; accompanying the nausea and vomiting there is pain in the left hypochondrium, back, and also in the lower abdomen; this pain is sometimes intense; it comes on in paroxysmal attacks lasting from one half to two hours, and is mainly experienced between 2 A.M. and 5 A.M. Eructations are almost constantly present and at times of acid. The patient believes that she is quite sallow following these gastric attacks, though she has never been jaundiced. The stools are sometimes light colored; the bowels are regular, the urine is high-colored and causes a burning pain on micturition and there is increased frequency in voiding. The patient has severe menstrual pain with decreased flow and pain in the lower abdomen, with a soreness on both sides extending around the back and down the legs, which is increased on walking or riding. She has become very nervous recently and complains frequently of sick headaches; she has lost considerable flesh and the appetite has been diminished. On examination the patient was found to be a fairly healthy looking woman with a fair amount of flesh; the tongue is clean, the mucous membrane of a rather good color; the skin is sallow and covered with some acne pustules, especially on the back. The chest wall is well formed, the movements are good; the heart and lungs are normal.

Inspection. — The abdomen is full; there is considerable subcutaneous fat; the left side of the abdomen is a little fuller than the right.

Palpation. — The abdomen is tender everywhere; there is considerable muscular resistance in the left hypochrondrium; this area is exquisitely tender to pressure; the tenderness extends along the left costal margin, running from the axillary line 8 cm. toward the median line; no mass can be detected. There is also considerable tenderness in the lower abdomen, which is about equal on both sides. The liver is not palpable; the upper border extends to the fifth intercostal space; the right kidney is freely movable (2°); the left kidney slightly palpable; there are no glandular enlargements.

Percussion. — On auscultatory percussion the stomach is found in normal position and not dilated, the lower curvature reaching one finger's breath above the

* Read at the Annual Meeting of the American Gastro-Enterological Association, Atlantic City, June 4, 1907.

umbilicus. On inflation of the stomach a similar result was obtained.

Gastric contents. — One hour after an Ewald test breakfast 40 cc. of gastric contents were obtained of a cloudy appearance, but well digested, containing no remains of a heavy meal taken the evening before. The total acidity is 40; free HCl, 0.141%; pepsin and rennet normal. A second examination revealed similar results. The patient was placed on a liquid diet, the gastric disturbance was lessened, while the lower abdominal pains became so intense that the patient consulted Dr. W. W. Russell for relief of this condition. On examination, Dr. Russell could not detect any pelvic disorder, but finding a "suspicious" condition, ordered the patient to the Union Protestant Infirmary for examination under ether. The patient entered the hospital on Nov. 27, 1906. The following day she was placed under ether anesthesia, and inasmuch as the pelvic condition still remained obscure, an abdominal incision was made for exploratory purposes. The pelvic organs were found normal; the appendix and the gall bladder were also normal.

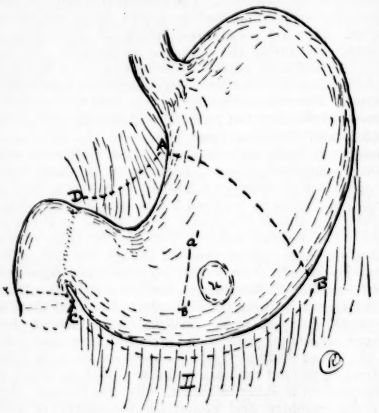

FIG. 1. D, A, B, C, Y, X, line of excision. A′ B′ exploratory incision. U, ulcer.

The stomach presented a mass on its anterior surface 1 cm. from the greater curvature and about one third of the distance between the pylorus and cardiac extremity. The mass was about 3.5 cm. in diameter, convex externally and concave on its inner surface. There were a number of hard shot-like glands above the lesser curvature of the stomach and below the greater curvature. A longitudinal incision 4.5 cm. in length was made along the pyloric side of the mass, the mass everted and then inspected. This was found to be an ulcerating mass with a firm fibrous indurated base, concave, and sharply circumscribed with elevated edges. Inasmuch as the base of the mass was indurated and thickened, and inasmuch as there were present a number of enlarged glands in the fat of both the lesser and greater curvatures, the question of malignancy could not then be definitely determined. It was therefore decided to perform a radical operation and remove the entire mass with its neighboring tissue.

Accordingly, after freeing the duodenum and stomach and carefully packing off the peritoneal cavity, clamps were placed and the stomach incised between them along the line AB, BC, DA (Fig. 1), care being taken to remove as many glands as possible with the mass without, however, interfering with the bile ducts; the duodenum was then cut between the clamps along the line *xy;* the excised portion of the stomach was removed; the upper end of the duodenum was then closed, which was followed by the closing of the open end of the stomach, after the second method of Billroth. A posterior gastro-enterostomy was then made. The duration of the operation was two hours and twenty minutes. The patient recovered slowly from the ether and awakened with considerable nausea; she vomited a small amount of bloody matter; salt solution enemata were administered every four hours. On the following day the temperature of the patient was 99°, pulse 76 and strong, and she was found in splendid condition; the nausea gradually disappeared, and on Dec. 1 the patient was very comfortable, had no nausea and was able to take small quantities of water by the mouth, and on Dec. 4 as much as half an ounce of any liquid. The patient gradually gained her strength, and her subsequent history was uneventful until Dec. 10, when a rise of temperature (100°) began to reveal itself with pain and muscle spasm in the left inguinal region; on the following day the pain extended down the inner side of the left thigh and was followed by a numbness in the leg. A phlebitis of only moderate severity manifested itself, which detained the patient in bed until Dec. 30, 1906, on which day she was able to be up in a chair. Coincidently with the phlebitis there was a dry pleuritic friction rub present in the right lower chest at about the center of the axillary line; this subsided within three days. The patient was able to walk and to leave the hospital on Jan. 12, 1907; her left leg was still somewhat swollen; her appetite and digestion were good. On April 10, 1907, a Ewald test breakfast was given; 44 cc. of contents were removed at the end of one hour, with a total acidity of 49, free hydrochloric acid 0.10%. The patient complains but little of any digestive disturbance and can eat a fairly good meal without discomfort, although she realizes that she cannot take a large quantity of food at one time. The specimen removed was carefully studied by Dr. J. C. Bloodgood, to whom we beg leave to acknowledge our thanks, both for his careful study of the specimen as well as for this report. The following is his report:

"*Pathology, gross.* — Excavated ulcer with elevated edges; glands enlarged with areas suspicious of metastases.

"*Microscopic.* — Ulcer, vascular, cellular granulation tissue; glands chronic lymphadenitis.

"*Gross pathology.* — The piece of stomach removed measures 11 cm. in length. It has been divided at the junction of the pylorus with the duodenum, and removed with a considerable mesentery of fat on its greater and lesser curvature. There is a palpable tumor 1.5 cm. from the greater curvature, 2.5 cm. from the lesser and about 3 cm. of healthy stomach on the cardiac side and 6 cm. on the pyloric side. There has been an exploratory cut in the anterior wall of the stomach to the pyloric side of the tumor. The peritoneum over the palpable mass looks perhaps less vascular than the peritoneum in other parts. It is distinctly fixed, however, over an area of about 1 cm., while the palpable mass is about 2 cm. If one places the finger within the stomach it passes over an elevated ridge, then into a superficial excavated area; with the index finger of the right hand in this cavity and the finger of the left hand on the peritoneum, one can feel between the fingers a narrow zone of dense tissue, thicker and firmer than the adjacent stomach, well, but distinctly more elastic and not as hard as cancer. When the two palpating fingers approach the borders

of this mass, it has a smooth, round edge and is distinctly circumscribed.

"When the stomach is turned inside out, the mucous membrane everywhere looks normal except in the region of the palpable tumor. We have here an elevated area, the borders of which are covered with mucous membrane. This area measures roughly 3.5 cm. At the top of the elevation the mucous membrane dips down in crescent folds and ends abruptly. The surface of this excavated area is smooth; it does not look like mucous membrane; it is pale, with some red areas. It has the surface appearance of a simple ulcer, and not that of a carcinomatous ulcer. It has the anemic appearance of a very chronic ulcer. When a section is made for a block, we find an appearance similar to the simple ulcer described by Bloodgood.[1] There is, first, on the surface a narrow zone of tissue less than a millimeter in thickness, which looks like a red line; then there is a zone of white, firm, translucent tissue 5 mm. in thickness; no epithelial alveoli can be seen in this. Then there is a zone 2 mm. in thickness with white fibrous tissue mixed with red muscle tissue.

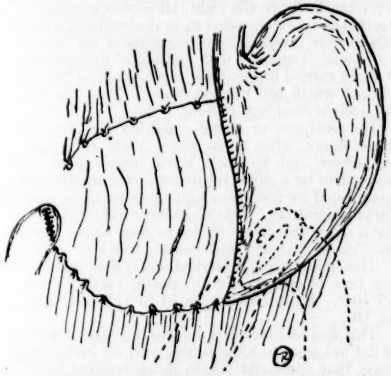

Fig. 2. Appearance of stomach after gastrectomy. E, position of gastro-enterostomy.

Then comes the peritoneum; here and there a streak of fibr ous tissue reaches the peritoneum."

"The tumor corresponds very closely to the case mentioned above and described by Bloodgood. In this case the ulcer is not as round, and there is less elevation of the mucous membrane around the ulcer, but the surface of the ulcer and the appearance of the tissue beneath correspond exactly to those in Bloodgood's case."

"When I first cut into the tumor, it was so firm that I hurriedly dictated cancer. It was slightly gritty, but not as much as is usually felt in cancer; the surface of the ulcer was too smooth, and in the rather edematous fibrous tissue there were no granular epithelial alveoli. The gross diagnosis of inflammatory tissue is confirmed by the frozen section. Between bands of fibrous tissue staining with eosin there are large areas of young connective tissue, quite edematous; at first sight one might say syphilitic ulcer, but the lymphoid-type cell does not predominate."

"One block was taken through the entire thickness of the ulcer for frozen, aceton and Zenker sections. One gland from the greater curvature and one from the lesser curvature. The gland in the greater has a white area exactly like metastatic carcinoma, but the white area cannot be expressed, as is usually seen in cancer. If I had cut into this gland at the operation, I would have made a diagnosis of metastatic carcinoma, yet from the finding so far we must look upon it as inflammatory. A large gland in the lesser curvature has a smaller white area, more of the appearance of a chronic inflammatory gland."

[1] Johns Hopkins Hospital Bulletin, vol. xv, November, 1904.

"This case illustrates the difficulty, at least with our present knowledge and experience, of making a correct differential diagnosis in doubtful cases at the operation. Even in the laboratory it required considerable time and careful inspection to come to the conclusion that the indurated area was an ulcer and not a schirrus carcinoma in an ulcer. When cutting into the gland in the laboratory it resembled a metastatic gland so closely that, were it not for the ulcer and the frozen section which are before me, I might look upon the gland as carcinoma. For this reason all doubtful indurated tumors which are operable should be treated as cancer when situated in the stomach, and I am of the opinion that in this case the functional result of the gastrectomy will be better than a regional resection of the indurated tumor. In the case just mentioned as reported by Bloodgood, a clinical diagnosis of ulcer was made. At the operation, on account of the indurated tumor and its infiltration of the fat in the lesser curvature, a diagnosis of cancer was made; in the laboratory a gross diagnosis of ulcer, which was later confirmed by the microscope."

This case is interesting from the fact that, notwithstanding the existence of a markedly

Fig. 3. Ulcer of stomach.

indurated ulcer in the stomach, the symptoms which were present were by no means distinctive of this condition, and that even upon direct inspection the simple ulcer could not be differentiated from a carcinoma. It is also evident, as Bloodgood points out, that all doubtful indurated ulcerations situated in the stomach should be treated as carcinomata, inasmuch as it is impossible in many of these cases to differentiate ulcer from carcinoma by simple inspection, and again because in a certain number of these cases a carcinoma is apt to develop upon the indurated border of an old ulcer.

Clinical Department.

TWO CASES OF BRAIN ABSCESS.*

BY F. E. KITTREDGE, M.D., NASHUA, N. H.

CASE I. John J. Nine years of age. A full-blooded Micmac Indian.

Entered hospital Aug. 24, 1906. Gave a history of long continued suppuration of right ear and frequent attacks of pain. At date of entrance to hospital there was marked edema and tenderness back of and just above the ear. I did a simple mastoid operation, finding the bone rather dense for a child and but very few cells. The mastoid antrum contained pus and necrotic tissue. In curetting the antrum, broke through the roof and exposed an epidural abscess, evacuating about a teaspoonful of pus. The dura was covered with granulations. Enlarged my opening on all sides until I came to what appeared to be healthy membrane, carrying it forward, somewhat over the ear.

The little fellow's symptoms all subsided, temperature became nearly normal and apparently made a good recovery. He left the hospital in about three weeks' time.

Sept. 22, I was called to his house and found him having at intervals very severe frontal headaches, accompanied by violent attacks of vomiting, slightly subnormal temperature and a pulse of about 60.

After watching him a day or two, I diagnosed brain abscess and urged his folks to return him to hospital for operation. At that time they refused, but a few days later, finding that his condition was growing worse, consented and I moved him there and operated Sept. 27. Temperature at the time of operation was 96.4 and pulse 58 to 60. There was no tenderness upon pressure anywhere on that side of the head.

I reopened my original incision and found the dura, which had been originally covered with unhealthy granulations, in a healthy condition, but somewhat bulging. I laid open the membrane, and went in about one inch with a needle but secured nothing. Then got a longer needle and going in fully one and a half inches or more, drew out a few drops of pus.

I then cut the brain tissue from below up, and evacuated over 1 oz. of pus. Carrying my finger in as far as I could reach, I found a well walled off cavity. Noticing a little pus posterior to my opening, probed and found another pocket. Upon opening this, I should think a half ounce of fluid was found and evacuated. The first pocket went directly in toward the center of the head and slightly upward. The second went almost directly backward, just above the ridge of the sinus. I drained both cavities with gauze, changing it once in twenty-four hours.

At the time of operation enough bone was removed so that I had an opening about two inches in diameter. After a few days he had a pronounced hernia and it was extremely difficult to keep it well drained. This gradually broke down and required considerable curettement. I hardly dare to say how much necrotic tissue was cut and curetted away, but finally secured a large and fairly clean cavity directly up to what appeared to be the wall of the ventricle, and extending backward, about as far as I could carry my forefinger. There was no loss of motion or function and the little fellow was very bright mentally.

He seemed to be doing well until about Oct. 15, when he developed meningeal symptoms which gradually grew worse. Just previous to this, when everything was apparently doing well, he was seen by Dr. Philip Hammond, of Boston, and we thought there was every prospect of a rapid recovery. The meningeal symptoms continued to grow worse, the head was drawn back, bowels markedly retracted, obstinate constipation, difficult urination and marked pain upon any movement of the body.

These symptoms continued for several days, and finding that my cavity had markedly decreased in size with bulging of its walls, I made a thorough examination with finger. The finger seemed to break into the wall of the lateral ventricle and, upon its withdrawal, was followed by a gush of water mixed with considerable pus. I then carried packing very deep, in same direction from which the water came.

Soon after this his meningeal symptoms seemed to subside, and general condition grew better. After some trouble, a movement of bowels was secured, and he was able to pass urine without difficulty.

Upon Oct. 25, when he seemed fully as well, he was suddenly taken with convulsive movements and these were immediately followed by absolute loss of power over limbs of left side of body. The face was apparently paralyzed upon that side, the mouth being drawn back very markedly to the right, there was grinding of the teeth, the eyes were rolled up in the head and wide open. There were involuntary movements of the bowels and urination, together with absolute unconsciousness. I again carried finger in and opened one of the original sinuses which had become closed. This was followed by a slight discharge of fluid.

He remained in above condition for about forty-eight hours, when there was a slight return of consciousness and he took some nourishment. There seemed to be a slight return of power in arm and leg, manifested by resistance upon moving them, a spastic form of paralysis. This slight improvement lasted only for a short time however, for he soon lapsed into absolute unconsciousness and died the following day.

This patient had a marked septic temperature from the time of operation until death, varying from 99° to 104°. Pulse varied from 70 to 125, averaging 100 to 110.

This was an extremely interesting case to watch, as it did not seem possible to me, with my limited experience, that one could lose so much cerebral tissue and have no motor or mental disturbance. I will not undertake to say how large a cavity there was, but when seen by Dr. Hammond, he estimated that about one third of the hemisphere had disappeared. I do not think that is at all overstated.

From an anatomical point of view, just what part of the different lobes of the brain were involved, I cannot say, except that the first large cavity lay in the tempero-sphenoidal region, a little above the floor, and extended well upward and inward. The smaller cavity extended directly backward toward the occipital region. Later, my small posterior cavity seemed to become obliterated, and I had one large cavity extending directly inward, its upper wall was high up toward the top of the head, and its posterior part, somewhat in the shape of a funnel, extending far back and toward the center.

Previous to the operation Dr. C. H. Nutter attempted an examination of the patient's eyes, but the boy was considerably frightened, and he could not do so satisfactorily.

CASE II. Luther S. Thirty years of age.

Entered the hospital Oct. 9, 1906. Temperature 101°, which quickly advanced to 104°. Had all symptoms of acute mastoiditis, including tenderness over mastoid region and just above left ear.

History of having had trouble with that ear since a boy, with slight discharge at times, also marked pain through that side of head at intervals.

* Read before the New England Otological and Laryngological Society, Nov. 16, 1906.

Had appearance of being a very sick man, and it was thought best to delay interference and watch him for a time. The acute symptoms gradually subsided, temperature became lower and he felt considerably better, all but the tenderness upon pressure, over and back of ear, which remained about the same. His general condition being very much better, Oct. 11, I operated, doing a simple mastoid. The bone being very much sclerosed, found it a very difficult operation. About one-third of an inch under the surface, opened up a cell which was filled with very dirty looking and bad smelling pus. A very small sinus connected that cell with the antrum, which also was filled with pus of the same character, and necrotic tissue. Everything was cleaned out as thoroughly as possible.

Patient rallied well, temperature became normal and remained so. He had every appearance of making a rapid recovery. There was just one symptom that caused me any uneasiness, and that was, now and then, pain at top and side of head, but after four or five days, that seemed to subside and he was allowed to sit up and move about. Upon the morning of Oct. 17, he felt so much better he was considering when he should leave the hospital.

Early that afternoon, one of the nurses noticed that he did not answer readily when spoken to, and very shortly after, had a severe convulsion following the cry which usually precedes that of epilepsy. The head was drawn back, mouth turned to right and eyes rolled up in head. The breathing was heavy and hard. One convulsion followed another for the next two or three hours, and were only controlled by frequent inhalations of chloroform. Patient was very drowsy during the remainder of the day. Following convulsion he had three or four attacks of vomiting. Next morning felt better, temperature was 99° and a fraction, pulse about 60. Calomel was given to act upon bowels and after several free evacuations he brightened up and declared he felt about as well as before the attack.

That night, his temperature going to 103° and pulse beating very slowly, I decided upon immediate operation for brain abscess. I trephined about one inch above the zygomatic ridge, directly in line with the mastoid, and had immediate bulging of dura through the lower part of my opening. Needle was entered immediately under the dura, no pus found, then was carried about one-half inch into the brain tissue, where it entered a pocket of pus.

Bone was then cut away with rongeur forceps, down to the original mastoid opening, dura was opened up, and with a knife cut into the brain until the pocket was reached. I found the cavity filled with very foul pus, should think about half an ounce in all. Depth of cavity was possibly one and a half inches from outer surface of brain. I cut away the roof of the mastoid, also roof of the tympanum, securing good drainage. For the first two days I used, as drainage, iodoform gauze packed in strips. Following that used a cigarette drain with plain gauze.

The discharge was very dirty and bad smelling for ten or twelve days, and he seemed a little dull mentally for about the same period. His temperature ranged from 98.5° to 99.5°. Pulse was very slow, most of the time from 50 to 56, until Oct. 29, when it was only 40. The following day, upon removal of dressing, much more pus was found than usual. My forefinger was very carefully carried into the cavity and the tip entered another pocket at the extreme end of and anterior to the original one. His pulse, soon after, began to improve both in character and rapidity of beat, going into the 60's, at times even above 70. This patient left the hospital Nov. 8.

There was marked pulsation of the walls of the cavity as far in as I could see with a reflected light. An interesting thing to observe upon examination was, that if the patient hawked or coughed ever so slightly, it was immediately followed by a wave of the walls of the cavity, and a quick bulging, due, I suppose, to a rapid hyperemia in the brain.

Oct. 25, Dr. Nutter examined the patient's eyes and gave the following report:

Fundus of right eye normal.

Left eye, a slight neuro-retinitis, involving about one third of the outer border of the optic nerve.

No hemorrhage or change in blood vessels noted.

GENERAL LYMPHO-SARCOMA ACCENTUATED IN THE PHARYNX.*

BY F. P. EMERSON, M.D., BOSTON.

April 30, 1901. Mr. A. C. W. was sent to me with the following history: He was forty-seven years of age, an American, born in Boston, and a merchant by occupation. His father died at the age of seventy-five from cardiac disease. His mother died at the age of seventy-four from carcinoma. One brother died of phthisis; one sister died of scarlet fever. The patient gave a history of having had typhoid and, at the age of eight, an attack of rheumatic fever, which recurred annually six or eight times.

In 1898, an intestinal hemorrhage was followed by fainting. There was epigastric tenderness and a consulting physician diagnosed duodenal ulcer.

In 1899, a fainting attack was preceded by hematemesis, and following this hemorrhage there first developed difficulty with articulation which grew progressively worse and was accompanied by hoarseness. At this time, examination showed a spare man, poorly nourished, with marked pallor and swollen upper lids, having the general appearance of pernicious anemia. There were no scars on the skin or mucous membranes. Glands were found in the groin and neck, but the spleen and mesenteric glands were not palpable. There was marked cardiac hypertrophy with a systolic murmur at the base. The rhythm, however, was regular and the compensation good. There was slight dyspnea. The uvula was club shaped and the size of one's thumb. A new growth, which seemed to be an extension of the posterior palatine folds, was seen in the lateral walls of the pharynx, with a central mass between. This mass protruded forward at the lower third of the pharynx, was resistant to the finger and of a grayish color.

The larynx was not involved.

The nares were obstructed completely, apparently from collateral edema which gave a tense and water-logged appearance to the mucous membrane. This did not shrink under cocaine sufficiently to afford a view of the pharyngeal vault.

The upper lids were puffy, especially at the outer third, where they formed a curtain over the eyeball. Eversion of the lower lids showed them to be thickly studded with granular elevations. There were nodules in the cheeks and to each side of the frenum of the tongue. The bridge of the nose was broadened. There was no history of pain, headache or sensitiveness of the scalp.

The patient denied syphilis and alcohol.

His weight had dropped from 158 to 130 lb., and later it fell to 126½ lb.

He had had so-called bilious attacks frequently, and such attacks always preceded tarry stools.

His temperature was normal and the pulse 80. There was loss of appetite with fullness of the epigas-

* Read before the New England Otological and Laryngological Society, Nov. 16, 1906.

trium and muscular weakness. Pallor and depression were marked. His station and gait were normal. A provisional diagnosis was made of syphilis of the uvula, posterior pillars of the palate and pharynx, and he was put upon mixed treatment.

Oct. 22, 1901. The patient had gained 2½ lb. During an attack of rheumatism, lasting two weeks, his physician reported that the hoarseness with difficulty in swallowing, and swelling of the eyelids, improved decidedly, but returned with convalescence.

Nov. 7, 1901. — His weight had increased to 132½ lb.

Nov. 15, 133½ lb.

Nov. 26, 134 lb.

Dec. 15. There was a slight hemorrhage from the stomach and bowels. At 12:45 and 1:45 there was loss of blood from the stomach. This was followed by improvement in the swelling of the eyelids and throat.

Jan. 23, 1902. The patient had another hemorrhage. Three days previous to this, he had had yellow, watery stools without epigastric tenderness. At this time, he had sharp stinging pains in the cartilage of the left ear. The nares were now open and he ate better, but was pale and weak.

March 4, 1902. The pharynx was more swollen laterally and at the lower third, and the patient had great difficulty in swallowing.

The lymphatics in the neck, cheek and eyelids were worse. The uvula was two thirds its former size and the nares clear. His pulse intermitted one beat in seven and he felt weak. The treatment had been stopped three times from acute attacks of influenza which he shared with other members of the family. This interrupted treatment so that it was difficult to estimate its value.

May, 1, 1902. Examination showed the urine and sputum to be negative. Examination of the blood gave hemoglobin 75%, whites 6,800, reds, 3,568,000. There was no increase in the lymphocytes.

A microscopical examination had been made May 17, 1901, by Dr. H. C. Low, of the Boston City Hospital, from a snipping from the posterior wall of the pharynx. He reported as follows: Gross appearance of a spreading growth on the posterior wall of the pharynx, growing down on two sides in ridges as large as the little finger. Piece taken from the growing edge lower down.

Microscopical description. — A round cell growth very much resembling lymphoid tissue, showing very few mitotic figures and of evident slow formation. It has for the most part a definite capsule, but in places is infiltrating the muscle tissue. The clinical history must be relied upon to determine its malignancy. A large definite tumor growth would suggest sarcoma. This section was afterwards seen by two other pathologists, and pronounced undoubtedly lympho-sarcoma. At this time, the treatment was changed to arsenic and he was put upon Fowler's solution which was gradually increased to 15 minims t. i. d. This was continued for a year, then omitted for a year and then resumed for two weeks, and then again omitted. It was twelve months before there was any decided change. The throat was then better, but he was thin and weak and had given up his business interests.

Examination, Sept. 25, 1905. Three years later the patient showed no spleen, and his general physical condition was negative, except for the old heart lesion which was not giving symptoms. Locally, the nasopharynx was entirely clear. The bridge of the nose remained broad, and the eyes, which for the last twelve months had been entirely normal, had just begun to be puffy again. It was for this that he again consulted me. He had had no hemorrhage for four years. There were no glands, pallor or muscular weakness. His appetite was good. His weight was 154 lb., which was normal. The blood showed no abnormal cells and the leucocytes were not increased. On account of the returning puffiness of the lids the arsenic was resumed.

Oct. 25, 1905. There was a hemorrhage from the left naris, which saturated two handkerchiefs. This relieved the previous blocking of the left naris but not on the opposite side. A few weeks of the arsenic treatment was followed by normal conditions.

Nov. 17, 1906. The patient was shown at a meeting of the N. E. Laryngological and Otological Society, and the members concurred in the probable diagnosis, although there was then no clinical evidence of the local process.

May, 1, 1906. For the past year, Mr. W. had been better than for five years. He had been of normal weight, good color, bright mentally and had been able to take active interest in his surroundings, although he had retired from business.

April 13, 1906. While in his carriage house with his son, the suspended shafts of the carriage fell, knocking off his hat and grazing the left side of his nose from which a drop or two of discolored serum exuded. It was not enough to attract his attention until noticed by his son. On Sunday, the skin became red and edematous accompanied by a chill and a temperature of 102.5°. Monday this area became circumscribed and as it fluctuated, it was opened under ether by his family physician, and pus evacuated. One week later, after some pain of the joints, thick pus was again evacuated.

April 27, 1906. The patient complained of a fullness of the throat. This was followed by a profuse discharge and evidence of collapse. In the afternoon, there was more discharge so abundant that his physician thought that he would choke to death, and which was described as a frothy mucus which appeared as fast as it could be wiped from the mouth.

May 7, 1906. I saw him in consultation. At this time, his temperature was 100°, P. 96, R. 28. His pupils were contracted. He was delirious but spoke intelligently on being aroused. Examination did not reveal anything abnormal in the naso-pharynx or throat.

May 10, 1906. I saw him again and his condition was one of coma from which he could not be aroused. Death followed about noon, apparently from toxemia.

Reports of Societies.

NEW ENGLAND OTOLOGICAL AND LARYNGOLOGICAL SOCIETY.

MEETING HELD AT THE BOSTON CITY HOSPITAL, NOV. 16, 1906.

THE President, DR. F. L. JACK, in the chair.

DR. F. E. KITTREDGE, of Nashua, N. H., read a paper on

TWO CASES OF BRAIN ABSCESS.[1]

DISCUSSION.

DR. F. B. LUND: It seems to me that these cases which have been presented are very brilliant ones. The majority, as we know, arise from ear disease, and the fact that they have had a suppurating ear is very important in making the diagnosis. But now and again cases occur where, if the ear is not suppurating, it is difficult to tell where the brain abscess started. The symptoms are very like those of brain tumor; many have no temperature, the only symptom you are sure of

[1] See page 396.

is very bad headache and usually vertigo, and about 35% have optic neuritis. The patient usually has slow cerebration. In fact, many of the symptoms may be absent, making the diagnosis difficult.

Now, as we know, Virchow has pointed out that brain abscess is frequently secondary to disease in the lungs and pleural cavity. I have specimens of two cases, removed at autopsy, which came into this hospital on the surgical side only two days before they died. The cerebellar abscess was a sailor who had been sick seven or eight days in a typhoidal condition; he had headache, a certain amount of dizziness and one night fell out of bed. Our examination was negative. An abscess was found in his cerebellum, which is there on the table. No lesions were found in his body except in the pleural cavity; from adhesions there he may have had an old abscess.

Another case, a little girl, with abscess of the white matter of the temporal lobe, came to the hospital two days before she died. She had been sick four and a half months with symptoms of some disease in the left temporal lobe. The only thing that was known to indicate that she had lung disease was that she had once expectorated blood in large amount. Dr. Bullard made a diagnosis of cerebral tumor. She had no temperature, but she died after being here two days and at the autopsy disclosed this abscess in the white matter and a pin imbedded in the lung. The cerebral abscess was secondary to an abscess in the lung, undoubtedly.

Now the question of drainage. I have operated personally on but two abscesses: one was secondary to compound fracture, and died, and the other to ear disease, and although the abscess was in the temporal lobe it was a very acute affair, and he died three days after the drainage was put in. I think that other things being equal, a case of long standing, a chronic case, is more apt to recover because the bacteria are less active than in the early acute ones. The question of drainage of the brain is a very difficult one. As Dr. Kittredge has said, the brain falls in and shuts off the drainage tube, and if you pack it with gauze it does not drain well. In a case I have recently had I drained with a roll of rubber tissue, but it was not successful. The cause of death was meningitis, which spread down the spine from the membranes of the brain.

The director that Dr. Leland put in nine different directions in the brain I do not think is a very good instrument. I do not like it because the hole in it gets plugged; a little thick pus will plug a hole like that. I think if you use a grooved director and pass it with another director and follow along the curve, then separate them a little, you get a very good instrument to locate pus. But the question of drainage I hope to get some light on, and I think it one of the most difficult questions that we have to meet, how to drain a cavity in the brain tissue.

Dr. P. C. Knapp: Dr. Lund said very justly that the diagnosis of brain abscess is an extremely difficult thing, and that is especially true with latent abscesses. The symptoms, with the exception of the fever and of the chills, which are by no means constant, are often very similar to those of brain tumor, excepting that an optic neuritis is not quite as common.

In the otitic abscess we have considerable help in the diagnosis by discovering the existence of a suppurating ear, and especially if the suppurating ear is only on one side, but in the cases where both ears suppurate the diagnosis of the abscess is often much more difficult. In those cases I think the local pain and local tenderness are a very distinct help, although by no means infallible. Again we are helped a good deal by knowing that as a rule the otitic abscess occurs in the temporal lobe, or in the cerebellum, and it is often possible after operating on the ear and following up the suppuration to follow directly up to the abscess. Unfortunately in many of these cases the diagnosis becomes difficult from the fact that, on the right side in particular, the lesion of the temporal lobe is apt to cause no definite localizing symptoms; the same is true of abscess in the cerebellum, and therefore we must depend largely upon the location of the pain and tenderness, and possibly upon the symptoms from disturbances of adjacent parts. In one or two of the cases reported to-night the existence of a localized convulsion beginning in the face would, of course, be an indication of an abscess in the temporal lobe. On the other hand, a partial hemiplegia, I think, is more apt to occur with cerebellar abscess than with abscess of the temporal lobe. Any indication of a cerebellar ataxia is, of course, another help, but it is rather by the occurrence of a number of symptoms pointing either to the temporal lobe or the cerebellum that we are helped the most.

There is rather a curious feature about these very brilliant successes in brain surgery that have been reported here to-night, namely, the very great destruction of the temporal lobe without serious consequences. I do not see how there could have been very much left of the temporal lobe, and it was the left temporal lobe besides, in Dr. Leland's case, and yet he assures me that there is no intellectual disturbance and no speech disturbance. In the other cases which have been reported, in spite of the destruction of a considerable portion of the temporal lobe by abscess, as in Dr. Jack's, with a temporary aphasia, there has been no permanent loss of speech function. In cases of tumor of the temporal lobe it has been my experience that, even when on the right side, the disturbance of the intellectual function has been very great, as great if not greater than in tumors of the frontal lobe. Such cases as this of Dr. Leland's particularly seem to afford some corroborative evidence of the very heretical stand which Marie has taken on the subject of aphasia, that there is no such thing as aphasia; it is not a true loss of speech, but is simply a condition of mental failure due to the lesions.

Dr. F. L. Jack: In August, 1901, a patient was brought to the Eye and Ear Infirmary, moribund, having been in this condition for several hours. Diagnosis of brain abscess was made from the history and symptoms. He was put on the operating table, and the floor of the middle fossa, for a half inch in width, was removed as far as the tegmen of the antrum. A small spot of discoloration was found on the dura, and through this a very thin bladed knife was thrust, opening a very large abscess cavity in the temporosphenoidal lobe. When the pus was evacuated the pulse and breathing apparently stopped. Patient revived, however, but was not in a condition to have a radical operation performed.

There are one or two interesting things in connection with this case. He exhibited amnesic aphasia, which persisted for several months, gradually disappearing. His occupation is that of a newspaper reporter. He had also another complication, viz., epileptic seizures, or rather seizures of epileptic form. Dr. Knapp takes exception, I think, to calling this epilepsy. The patient is to-day perfectly well. For perforating the bone, the old trephine is still largely used, but we find at the hospital that the Krause bone-cutter is better.

Dr. Philip Hammond: The amount of brain tissue that must have been removed in the case of the small Indian boy was really astonishing. I have myself made various holes in the head and know that a certain portion of the brain may be removed with impunity, but, as I say, it was perfectly amazing to see the size

of the hole in this little chap's head; I think I could easily have placed one of my fists in it could I have got my hand through the opening.

DR. KITTREDGE: I think my little Indian boy had had an abscess there for some time. His pulse was very slow, down to 60 a good deal of the time, and he had an attack of vomiting that I laid to some indiscretion of the diet, but as I look back on it I think he had an abscess in the brain at that time. There was no odor to the pus in his case.

About the drainage,— in the second case I had a small-sized cigarette drain at the opening, and then I carried a piece of gauze right above the cigarette, so I practically had double drainage there.

DR. FRANCIS P. EMERSON, of Boston, read a paper on

GENERAL LYMPHO-SARCOMA ACCENTUATED IN THE PHARYNX.[2]

DISCUSSION.

DR. S. B. WOLBACH: The original sections present all the characteristics of a malignant lymphoma, that is, a malignant tumor composed of cells resembling active lymphoid cells, such as are found normally in the germinal centers of lymph follicles. In this case the sections show invasion of the muscles and mucous glands of the soft palate.

At the autopsy nothing remarkable was found. There was no trace of a new growth. Two small nodules were found in the aryteno-epiglottic folds, and microscopically these consisted of hyperplastic lymphoid tissue without suggestion of malignancy. Nothing was found to explain the symptoms which appeared a few days before death. The brain was negative. The source of the intestinal hemorrhages was not discovered. The abdominal cavity was filled with embalming liquid and escaped intestinal contents. The viscera were full of perforations made by the undertakers so that we were greatly handicapped in making the autopsy.

The lymphomata have recently been grouped under the heading of lymphocytoma. This term includes tumors arising from lymphoid structures and from the bone marrow. The literature is very voluminous and the terminology employed by the different authors very confusing. Of the various names proposed for tumors similar to the case of Dr. Emerson, I think lympho-sarcoma is the preferable one.

A number of cases of spontaneous cure of lympho-sarcoma have been reported while many have been reported as cured after treatment with arsenic. Some cases which were apparently cured with arsenic have recurred and ended fatally after several years. This case with the presence of enlarged glands might possibly be called a case of Hodgkin's disease. The term lympho-sarcoma is a better one, especially as a number of pathologists reserve the name of Hodgkin's disease for tumors with special histological features.

The age in this case is unusual. In a list of 58 cases, only 4 occurred between the ages of forty and fifty, while 27 occurred between the ages of ten and thirty.

DR. J. P. CLARK: I should like to ask if the case did not improve under specific treatment at first, and if so, could syphilis be ruled out?

DR. G. L. RICHARDS: I recently had a case where a diagnosis was made of syphilis and of tuberculosis. The patient has improved under arsenic treatment very steadily. Clinically, I think this was sarcoma.

DR. EMERSON: In my own mind I was very much dissatisfied with the result of the specific treatment, for the reason that just as the patient would begin to gain he would come down apparently with an acute infection. That this infection was due to influenza seemed probable as his wife and son were simultaneously affected. This necessitated the calling in of his general practitioner and the interruption of specific treatment so that it was not followed as continuously as it should have been.

DR. EMERSON presented a paper on

SARCOMA OF TONSIL TREATED WITH COLEY'S TOXINS.[3]

DR. E. W. HOLMES showed a case illustrating

A SPECIAL SKIN FLAP.

This case was operated on two years ago last February for a simple mastoid, and made slow recovery. On the 5th of September, this year, he was returned to the hospital, and his condition was such that it was thought best that he be operated on again at once. I showed him, to illustrate, a special kind of skin flap that I had been making. I did not think it could be done in this case because there had been an operation and there were adhesions, but I was able to make the flap and adjust the same and he was able to leave the hospital in two weeks, and now he has a perfectly dry ear, with perfect epidermization.

I have done this operation in 31 cases, and I hope to be able to show many of them. It saves considerable time in convalescence and in only one or two cases has the skin sloughed. The usual semilunar post-aural incision is made but through the skin only, care being taken not to injure the underlying periosteum. The anterior skin flap is now dissected from the periosteum and posterior and superior cartilaginous wall of external auditory canal is incised. The whole auricle is carried forward exposing the bony auricular canal. An incision is now carried from junction of superior and anterior canal wall down to annulus, then just outside and parallel to annulus to junction of inferior and posterior quadrant of canal, and then extended outward to outer rim of bony canal. An incision is now made from this point over mastoid toward tip, and another from the anterior superior starting point along linea temporalis. We have now to elevate and have a flap made up of all of the periosteum covering mastoid bone and the skin and periosteum covering superior and posterior walls of auditory canal. This is rolled back and protracted with gauze in normal salt solution during the operation upon the bone. After this is completed the flap is carried forward and adjusted in middle ear. The cartilaginous canal attached to auricle is slit so as to produce a large canal for subsequent treatment of ear and the post-auricular wound is closed with sutures.

TRANSACTIONS OF THE TWENTY-NINTH ANNUAL CONGRESS OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

HELD AT WASHINGTON, D. C., MAY 7, 8 AND 9, 1907, IN CONNECTION WITH THE SEVENTH TRIENNIAL CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

(Continued from No. 11, p. 372.)

SECOND DAY (continued).

MODERN PROCEDURES IN EXCISION OF INTRINSIC MALIGNANT GROWTHS OF THE LARYNX.

DR. J. SOLIS-COHEN, of Philadelphia, presented this paper. He said that modern procedures virtually exclude all endo-laryngeal methods. This procedure comprises a central division of the thyroid cartilage and sometimes of the crico-thyroid membrane, cricoid cartilage, or even of the trachea, as may be requisite to fully expose the morbid mass and its immediate surroundings when the wings of the thyroid cartilage are

[2] See page 397.

[3] Laryngoscope. See March, 1907.

separated with retractors or with stout loop ligatures. He regards preliminary tracheotomy as not requisite except where strong indication existed for precautional use of a tube after operation. The whole may be done under either local or general anesthesia, choice being dependent in great measure on the location and apparent extent of the neoplasm and in part on the predilection of the operator. The author then described in detail the steps of the modern operation. He prefers to follow his own method of beginning with an ordinary tracheotomy, and after introduction of the canula to incise the skin only so far as to uncover the larynx, thus leaving a broad bridge of skin above the canula. This lessens considerably the dimensions of the external wound and favors reunion in the sequence. The bridge can be sacrificed if necessary. In his own practice no stitches are taken in the skin wound. Instead, a longitudinal strip of perforated plaster is placed along each side of the neck an inch from the line of incision, and then this plaster is sutured in several places along the line of thyrotomic incision through the perforations and tied only so tight as to bring the severed edges of skin to gentle apposition and leave the wound free for easy and immediate inspection. No threads are passed over the line of tracheal incision which is left bare to favor expulsion of matters from the air passages. A pad of gauze is moistened in bichloride solution while a broad strip of antiseptic gauze is doubled over a narrow strip of adhesive plaster and secured to the next so that the gauze hangs down over the dressing upon the seat of the wound. Post-operative treatment is most important and a skilled assistant should be on hand for the first twenty-four hours. Should it become necessary to re-introduce the canula in the trachea for any length of time, the atmosphere near the head of the bed must be moistened so as to prevent desiccation of secretion. The author paid a generous tribute to the recent work of Semon and Butlin. Dr. Cohen's chief points of variance from the usual methods are the retention of the skin-bridge above referred to, the removal of the growth *en masse* upon a plate of excised perichondrium and superjacent tissue, dressing with compound tincture of benzoin, avoidance of sutures in the cartilage and skin and the special method of loosely approximating the edges of the incisions. The tincture of benzoin is mopped thoroughly on the raw surface left after removal.

NON-RECURRENT CARCINOMA OF THE LARYNX, REMOVED THROUGH THE NATURAL PASSAGES.

The report of this case was made by DR. E. FLETCHER INGALS, of Chicago. The patient was a man of forty-four years, laborer, who came under observation in January, 1906, complaining of hoarseness of six years' duration. For the last three weeks he had felt some pain in the region of the left half of the hyoid bone, none previously. Had had also a recent catarrhal cold. There was no dyspnea but he could not talk as a rule much above a whisper. Had formerly been a mild smoker. Had lost a pound or two and had a slight hacking cough. A pinkish gray tumor involved the anterior $\frac{2}{3}$ of the left vocal cord filling the ventricular opening and considerably obstructing the glottis, crowding outward into the ventricular band. The growth had the appearance of malignancy, but owing to its long duration the author hoped it was only papillomatous. The greater part of it was removed at the first sitting. Three days later more fragments were removed and there was considerable pain felt by the patient in the larynx in the subsequent days. The patient was not seen again for a week, and in the meantime the microscopist had reported that the neoplasm was a slowly growing carcinoma with growth toward the surface and considerable kerato-hyaline transformation of the epithelial cells. At this time Dr. Ingals found a growth at the anterior end of the left cord larger than at the last visit, and this was thoroughly removed with a Mackenzie forceps. After removal of this a growth of about the same size was seen just below the cord and it was also removed. When the patient returned four days later he was very hoarse. Sedative measures were instituted and continued for several months. The patient's condition gradually improved and in two months it was noted that the voice was much clearer. The patient was again seen over a year after the operation, and for the last three or four months his voice had been perfectly normal. A slight thickening of the cords was noted but was referred to a recent cold. Dr. Ingals stated that although interference with malignant laryngeal growths is likely to stimulate their increase, it appeared to him that when there was doubt as to exact nature and when conditions were such that we had a hope of removing the neoplasm thoroughly by the endo-laryngeal method, this latter should be selected. If the examination revealed malignancy and the tumor speedily returned, laryngotomy or laryngectomy should at once be advised if there was reason to believe that a thorough removal could be effected.

EPITHELIOMA OF THE LARYNX; REMOVAL BY THYROTOMY; NO RECURRENCE AFTER THREE AND ONE-HALF YEARS.

DR. HENRY L. SWAIN reported this case, his patient being a clergyman of forty-seven years who came under observation in March, 1903, with increasing hoarseness dating back several months. The larynx was slightly congested throughout and much swollen on the entire left side so that no clear view of the true cord could be had. Subsidence of the swelling later revealed a white papillomatous mass growing from the upper aspect of the cord and apparently coming out of the laryngeal ventricle. Nearly the entire cord was covered by the growth. After some training of the patient the entire visible mass was removed in small pieces as it proved very friable. Microscopical evidence was negative. Some two months later the mass returned and was again removed. This was done five times in the next two months. Six months after the first appearance of the patient it was decided that something more radical must be done. Up to this time no positive evidence of malignancy was manifest under the microscope. Thyrotomy and exsection were then done after the usual modern methods. Recovery was rather slow but satisfactory. At the present time the patient speaks in a perfectly audible but rather husky voice. A fairly good presentment of a vocal band has been produced in the shape of a dense white band where the true cord should be. The false cord is flatter than usual and the ventricle has been obliterated. The reporter laid emphasis on the following points: 1, the ever present difficulty in coming to a diagnosis. 2, the wisdom, even when in doubt, of operating so as to insure complete removal. 3, the repeated observation of the surprising difference in the appearance of the growth when the larynx is opened. 4, the impossibility of being sure everything malignant has been removed; hence the value of using the Paquelin cautery. 5, the possibility, when the larynx is roomy, of shutting up the whole wound instead of leaving the tracheotomy tube in place. 6, the unquestioned advantage of the absolutely recumbent position with the feet raised. 7, the small amount of suffering in an intelligent, brave and tractable patient as compared to the mercy of a complete cure.

The papers of Drs. Cohen, Ingals and Swain were

discussed together. Dr. Ingals saw no reason why cocaine and adrenalin should not be used together so as to obviate so much mopping. He had had many disagreeable symptoms following cocaine. The adrenalin might prevent the absorption of the cocoine and thus prevent constitutional effects. An excess of gum benzoin, say 2 dr. to the ounce, was an advantage as it made a firmer film over the tissues.

DR. THOMAS HUBBARD had observed that in etherized patients adrenalin did not produce ischemia, at least in the nose. He did not know any reason for this. He had not made the same observation with reference to chloroform.

DR. J. PAYSON CLARK gave the history of a case of laryngeal cancer operated on ten years ago. The patient was still living at seventy and was in good health with a very firm, strong voice. A similar case history was given by Dr. Gordon King, of New Orleans, his patient being alive and well two years after operation, and with good voice.

DR. R. C. MYLES believed that there was something individual in these cases. The cancer might be of the superficial type and a good result follow operation, but he did not believe that cancer of the deeply penetrating type could be cured.

DR. D. BRYSON DELAVAN, of New York, gave the history of a case illustrating the fact that the picture as seen in the mirror gave a very misleading idea as to the extent of laryngeal involvement. His patient had been operated on ten years ago and was still in fair condition. Some of the surgeons of the present day were coming to the conclusion that cancer did not admit of cure. The time limit was not to be relied on. When we place it at three years we are in error as experience frequently shows. Under the method as presented by Dr. Cohen we were likely to secure the best results. He thought, however, that all methods were hopeless and in the main disappointing. We should continue our investigations in the hope of discovering some cure which would put surgery out of the field entirely.

DR. J. PAYSON CLARK stated that an operation which would prolong life was often justified even if it eventually proved fatal. He related the history of one case.

DR. COHEN closed the discusssion.

Case reports by DR. CLEMENT F. THEISEN, Albany, N. Y.

EPITHELIOMA OF THE LARYNX; TOTAL LARYNGECTOMY INCLUDING REMOVAL OF A PART OF THE TRACHEA; DEATH FROM PNEUMONIA ON THE THIRTEENTH DAY.

CASE I emphasized the necessity of early diagnosis and also the fact that microscopical examination is often difficult and that the laryngologist may lose valuable time owing to the pathologist's uncertainty. The patient was a man of fifty-seven years with a husky voice for some months. A flat, nodular, firm growth was seen involving about two thirds of the left cord. Surrounding parts were reddened. Examination of small fragments suggested that the condition was merely inflammatory. The reporter's original diagnosis, naked eye, had been carcinoma. Under palliative treatment there was temporary improvement, but some weeks later it was noted that the whole of the left cord had become involved and there were evidences of encroachment on the right cord also. The diagnosis was now positive and the dyspnea had become so great that a tracheotomy was done under local anesthesia.

After some delay on the patient's part he consented to a radical operation. A total laryngectomy (Gluck) was done three weeks later. Pneumonia proved fatal on the thirteenth day. The microscope showed typical epithelioma. It is worthy of note that the marginal epithelium of the growth was found in a normal condition, but its transformation into malignancy could be definitely seen in the sections. The growth itself was entirely of epithelial origin, and irregular columns of spheres of epithelial cells could be seen growing into the underlying tissue in all directions. In the centers of these areas there was manifest a tendency to rapid degeneration for the cells were in many places replaced by detritus. The interstitial connective tissue was thickly infiltrated with small mononuclear leucocytes and plasma cells and in some areas there was proliferation of the small capillaries.

CASE II. *Sarcoma of the pharynx.* — The patient was a girl of eight years with a history of dyspnea for several months. A large mass was seen in the throat, including the soft palate and pushing it forward. The growth extended almost to the epiglottis and apparently involved the naso-pharynx. Glands were enlarged on the left side of the neck. It was decided that the case was inoperable and the mixed toxin injections were given. Microscopical examination of a piece of the growth was not decisive. Clinically there was no doubt as to malignancy. Injections directly into the mass were begun and after some time constitutional reaction was noted. Adrenalin injections were not used as the method was too slow to effect any result in this case. The iodides were also without result. Nothing seemed to make any impression whatever on the growth. Death came from increasing dyspnea about two months after the patient came under observation. The microscope showed spindle-celled sarcoma with hyperplasia of adjacent lymph nodes. The reporter referred to similar cases recently recorded in the literature of sarcoma.

THIRD DAY, THURSDAY, MAY 9.
SESSION AT 10 A.M.

THE PROBLEM OF ASEPSIS IN THE ROUTINE OFFICE WORK OF THE LARYNGOLOGIST.

A paper on this subject was read by DR. THOMAS HUBBARD, of Toledo, Ohio. He made a plea for the same aseptic precautions in office work as in major surgery, and believed that in future more of the minor work now done in the office would be transferred to special hospitals. Most of our office work is now done under conditions which do not measure up to the requirements of modern aseptic and antiseptic surgery. All operators have experienced anxiety over cases having symptoms of sepsis, and cases of delayed healing arise which cannot be accounted for by defective operation. He then presented detailed features of office routine which he considered essential, dwelling on disinfection of instruments, sterile solutions, napkins, care of instruments to prevent rusting, etc., sterilization of the area to be operated on, avoidance of too firm packing, quality of air used in atomizers and air tanks, etc. A little trouble taken in all these respects would remove practically all the possibly injurious factors which exist in the routine of the office as ordinarily carried on. The surgeon in whatever special field or working environment must bear in mind that only by high ideals in the refinement of cleanliness, in both theory and practice, can he expect to stimulate his assistants and associates as to the proper discharge of their part of the work. The aim of every operator should be to develop a thoroughly consistent system of approximately surgical cleanliness.

DR. GORDON KING presented a device for sterilizing sprays in office practice. He had been very much interested in Dr. Hubbard's statements in regard to the sterilization of instruments and of the air. Filters placed over the ends of sprays showed conclusively that as ordinarily used the spray must project many micro-

organisms over the operative field. Dental napkins were of much service in office work but paper napkins could be used instead and they were practically sterile.

Dr. W. F. Chappell, New York, spoke of the danger of infecting the doctor from the sputa of patient. He himself had had a septic dermatitis of the face, eyes and neck during the past winter from the expectoration into his face by a patient of pus from an old pharyngeal abscess.

Dr. George L. Richards suggested the use in such cases of ordinary automobile goggles which could be made to hold a gauze mask.

Dr. R. C. Myles was accustomed to cover his patient and himself with a special kind of oiled silk. He frequently had a nurse hold a pane of glass before his face during operations. Such a device was more convenient than a glass shield suspended from the ceiling. Instruments must be boiled frequently. Asbestos-packed syringes were the only ones meeting all requirements. It was true that we had no definite knowledge of the occurrence of much sepsis occurring in office practice, but it was possible that there were some forms of septic conditions not localized in their manifestations.

Dr. Hubbard closed the discussion, stating that where there was a chance of doing an aseptic operation we should sterilize our hands and wear rubber gloves.

A review of the methods in use for the removal of adenoids with a description of a method which is thorough, rapid and safe.

This review was presented by Dr. George L. Richards, of Fall River, Mass., who exhibited a large collection of the various instruments employed for the purpose. He thought that undue stress had been laid on the necessity of cleaning out the fossa of Rosenmueller on account of its effect on the ear. His own preference is for the adenotome of Schuetz which had been presented to the Association some years ago by Dr. Farlow. It finds its best employment in young adults without anesthesia. The operator should have three sizes as there were but few pharynges in which one size or the other would not answer every requirement. In case of young children under anesthesia, and held in the arms of the nurse, a palate hook should be used so as to gain a good idea of the size and exact location of the mass to be removed. A little side dissection of the growth with the finger toward the center aids in getting it within the fenestrum. The instrument is then pushed firmly back against the naso-pharynx and as the knife cuts through the growth comes out in one piece. Instruments of different sizes may be used in the same case if necessary to remove small fragments left after the main cut. The adenotome is a slender instrument and the knife may occasionally break. The instrument should be carefully examined before each use and care is also required in taking it apart and putting it together again.

Dr. John W. Farlow recalled a previous meeting of the Association at which he had presented the adenotome advocated by Dr. Richards. The disadvantage of the instrument was that we could not well see into the naso-pharynx and determine just how large an instrument should be used. Hence he did not prefer the adenotome for very young children. In proper cases, however, the guillotine seemed to him to be the ideal instrument.

Dr. D. Bryson Delavan said that his experience with this particular instrument had not been fortunate as he had had one break leaving a portion of the metal in an adenoid mass. Fortunately, it was removed without untoward incident. One objection was that the pharynx has to fit the instrument whereas the latter should fit the pharynx. His own preference was for the Frothingham modification of the Gottstein knife. Hard rubber palate retractors were preferable to those of metal. He believed that it was absolutely necessary to thoroughly clear out the fossa of Rosenmueller in order to obtain relief from ear symptoms.

Dr. W. K. Simpson, New York, was also an advocate of the Frothingham curette. The Concannon forceps he thought to be the best model of this class of instrument. It had a guard which enabled the adenoid to be removed in one mass.

Dr. L. A. Coffin believed that the success of any instrument depended largely on the "man behind the gun" and his experience. There were very many poor models on the market of good instruments which had been changed by the makers from the original models.

Dr. Henry L. Swain was also a partisan of the adenotome. If, however, we had in the naso-pharynx a central mass on two sides we were liable to miss with this instrument the side strings from the main masses. The adenotome ought to be followed up with a blade-curette.

Dr. W. E. Casselberry had used the adenotome for a long time but was not satisfied with it. There was a liability to leave small pieces of tissue behind the posterior nasal openings. Some sort of supplemental operation was therefore necessary. This was a limitation of the efficiency of every adenotome he had ever seen. The adenotome would answer if used with the curette.

Dr. G. A. Leland said that unless the fossa of Rosenmueller was cleared out, there would be recurrent earache. Smaller instruments than we generally use would suffice for the purpose of cleaning out the fossa.

Dr. R. C. Myles said that the finger ought always to be introduced into the naso-pharynx in order to guide the intelligent application of any cutting instrument. The axis of the instrument should be kept in line with the axis of the head. Unless this was done, parts would be damaged. The fossa of Rosenmueller ought always to be cleaned out.

Dr. G. Hudson Makuen exhibited a modified Gottstein instrument which he had found of great service.

Dr. Richards closed the discussion.

(To be continued.)

Book Reviews.

On Treatment. By Harry Campbell, M.D. B.S., F.R.C.P. Pp. 421. New York: William Wood & Co. 1907.

This is a volume of 421 pages which seeks to discuss medical treatment from a somewhat psychological and, therefore, unusual standpoint. Such topics as the following, for example, are taken up: the education of the physician; the physician's mental personality (the word "mental" might well have been omitted); the co-operation of the patient; instinct and reason in relation to treatment; rationalism and empiricism. The latter part of the volume discusses certain general matters of hygiene, such as the therapeutics of fresh air, clothing, rest, diet, together with three chapters on psycho-therapeutics. It is increasingly evident that this latter subject will soon not fail to find a place in all discussions of treatment. In general, the book represents a personal standpoint, and in this fact lies its suggestiveness. We have no hesitation in commending it, particularly

to those physicians who look upon their professional work from a philosophical as well as from a practical standpoint.

Green's Encyclopedia and Dictionary of Medicine and Surgery. Vol. V. Pp. 536. Illustrated. Edinburgh and London: William Green & Sons. 1907.

The fifth volume of this encyclopedia carries the subject matter from "Inulin" to "Lumbar Puncture," and contains 908 headings. It also marks the publication of one half the entire work. The same principles which have been apparent in the earlier volumes are continued in this, namely, brief articles which are more comprehensive than are to be found in an ordinary dictionary, together with others which although hardly approaching the dignity of monographs, constitute admirable discussions of various topics. For example, the subject of labor occupies 150 pages, and really serves as a brief compendium of obstetrical procedure. The larynx, life insurance and the liver and kidney also receive a very considerable amount of space. In the section on joints, which is also fairly complete, we miss illustrations which would do much, if properly selected, to clarify this general subject.

A Treatise on Surgery. By GEORGE RYERSON FOWLER, M.D., Brooklyn — New York City — Examiner in Surgery, Board Medical Examiners of the Regents of the University of New York; Emeritus Professor of Surgery in the New York Polyclinic; Surgeon to the Methodist-Episcopal Hospital; Surgeon-in-Chief to the Brooklyn Hospital; Surgeon to the German Hospital. Vol. II. Containing 888 text-illustrations and 4 colored plates, all original. Philadelphia and London: W. B. Saunders Company. 1907.

Our attention has recently been called to the second volume of this noted work of the late Dr. George R. Fowler, a handsome book of 714 pages, excellently well illustrated. In this volume, the final volume of the set, the subject of regional surgery is completed. It is in some respects more fully presented than is usual in books of this class, and is classified in chapters devoted to the Surgery of the Dorsal and Lumbar Vertebræ; Abdominal and Pelvic Organs, including Genito-Urinary Surgery in the Male; Female Pelvic Organs; Upper Extremity; and finally the Lower Extremity.

The arrangement of the text is such that the important facts and headings of subjects are printed in heavy type so as to form an abridged classification or summary of the subject which is incorporated in the body of the work. In general, in presenting a subject the traumatic lesions are presented first, then the different acute and chronic pathological conditions, concluding with the neoplasms. Afterwards diagnosis, prognosis and treatment are considered. At times the description of the lesion or disease under consideration is full and complete. At times it is concise; essentially a mere summary. Frequently the authority for the statement made is given by quoting simply the originator's name. The chapter on peritonitis, while brief, is one of the interesting chapters, and presents the most advanced view of the subject. As one would expect from the author's interest in this lesion, the chapter on appendicitis is a full one, eight or more pages being devoted to the operative treatment which is extensively illustrated. Hernia is another subject which has been treated by an extended description. This includes the unusual varieties such as obturator, lumbar, diaphragmatic, sciatic, perineal and internal hernia; lesions which are rarely or only briefly described except in reports of special cases or monographs.

Again in the chapters on the male and female genito-urinary organs the author has treated the subject much more fully than is usual in a work on general surgery. Specific disease of the urethra, congenital defects, surgery of the prostate and minor gynecological operations are all included in this part of the volume.

In the section devoted to the upper extremity fractures, dislocations and other injuries, such as stabs, gunshot wounds, etc., are first presented. Next the different inflammations, acute and chronic, other pathological processes and neoplasms. Finally, the operative procedures indicated are given with the treatment. Each part of the upper extremity from the shoulder to the fingers is treated on this plan. The operative treatment includes the ligation of the arteries of the special region under discussion, also the amputation, resection of joints, operations on nerves, etc.

In the chapters on the lower extremity some attention is paid to orthopedic surgery. For reduction of hip dislocation Dr. Fowler has selected the "Allis" and "Stimpson" method; for amputations the "mixed method" with either lateral or antero-posterior flaps or the "Teale" operation; for the foot and ankle the operations of Lisfrans, Chopart, Piragoff, with modifications. Wladimiroff-Mikulicz, Syme and Heuter are described.

The book is a very valuable one; it is well arranged, clearly, concisely written, the subject is as a whole fully presented, it is profusely illustrated with well-chosen "cuts." Special subjects are easily found by the aid of the table of contents, the method of paragraphing of the text, the heavy type for important words and subject headings, and finally by a full general index. To write such a book an author must have a thorough knowledge of his subject, a knowledge not only theoretical but also practical, obtained only by great clinical experience. Dr. Fowler has combined both, for as a student of medicine he was conversant with medical literature; as a surgeon he acquired actual knowledge tested by great clinical opportunities; as a teacher he learned how to impart his knowledge to others. Hence his treatise on Surgery is a work which is universally spoken of as a task well done.

H. W. C.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 19, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

PHYSICAL CONDITION OF PUBLIC SCHOOL CHILDREN.

A BODY of prominent educators, made up of the Commission on Physical Welfare of School Children, has just made a report through its chairman, Charles C. Burlingham, formerly president of the New York Board of Education, in which it is stated that about one third of all the public school children in the United States are probably the subjects of physical defects which keep them behind their proper grades, and yet which should be remediable with proper care. Based on the physical defects and home conditions of 1,400 school children of New York City, says the report, it is estimated that 12,000,000 of the children have physical defects, more or less serious, which should receive attention from parents and physicians. If the percentages recorded by the Board of Health in New York should be maintained throughout the country (and it seems likely that they would be, since adenoids and impaired vision, malnutrition and defective breathing are found in rural as well as urban schools), there must be 1,440,000 ill-nourished children, 5,615,000 with enlarged glands, and 6,925,000 with defective breathing, in the United States. The defects indicated are easily remedied, and many could be prevented by proper care, though except in the case of defective vision the causes are not always readily determined. Among the 1,400 children studied, only a trifle more than 10% are reported to be suffering from malnutrition, and of these, fewer than 14% come from families whose income is less than $10 weekly. Only 7.8% of the children were artificially fed from birth, and while more than 50% are reported as having only tea or coffee and bread for breakfast, fewer than 3% are said to have no meat or eggs during the day. In spite of unfavorable housing conditions, only 19% of the children born in 1,400 families died, and 53% of the families have lost no children. The Italian and Hebrew families have the largest average number of children, and also the highest mortality. Comprehensive plans for dealing with physical defects are outlined in the report. These include a thorough physical examination of all children, notification to parents, and the enforcement of existing laws. Where proper authority is now lacking it is planned to compel parents to take necessary measures in behalf of their children's health. Enforcement of health, tenement house and child labor laws and the establishment, in connection with boards of education, of departments of schqol hygiene are recommended, the duties of which shall be to see that school buildings are so constructed and so conducted as not themselves to produce or aggravate physical defects. It is also suggested that the school curriculum should be so devised and carried out as not to favor such defects, that there should be a study of the effect of school environment upon the child, and that hygiene should be so taught that the children themselves will cultivate habits of health and see clearly the relation of good health and vitality to present and future efficiency and happiness.

Dr. Luther H. Gulick, director of physical training in the public schools of New York, has been doing most excellent work in improving the condition of the pupils, yet when the budget of $31,641,324 was approved recently by the executive committee of the Board of Education, one member objected to the proposed increase of Dr. Gulick's salary from $4,000 to $5,000. A striking commentary on such a pennywise policy is afforded by the following statement by Stratton D. Brooks, superintendent of Public Schools of Boston, quoted the other day in a dispatch to a New York newspaper: "I recently estimated that the City of Boston has been annually spending about $100,000 on pupils who, because of physical defects, did not derive full benefits from their work. I recommended that such a sum would better be spent on a department which would try to eradicate physical troubles."

In an address to the principals of the public schools of New York, made in the hall of the Board of Education on Sept. 10, Superintendent Maxwell impressed upon them strongly the necessity of more vigilant attention to the physical welfare of the children under their care.

He maintained that it was their duty and that of the teachers under them to make personal investigation of the condition of the children, and to urge upon parents the need of medical attention where physical defects were discovered. In speaking of the medical inspection of school children he said that every assistance should be given to the officers of the Board of Health in their work. Special attention should be given to four classes of pupils: To overaged children, to determine whether their intellectual development has been retarded by physical defects; to children who are very evidently suffering from physical defects; to incorrigible children, who have a tendency toward idleness and mischievousness; and, finally, to the persistent truant. "Last year," Mr. Maxwell went on to say, "I tried to have every boy examined by a physician before committing him to the truant school. My attention was called to the necessity for this by an investigation I conducted in the truant school. I had all the pupils examined by a physician of the Health Department; and there was not one who was not suffering from some physical defect. There can be no higher duty incumbent upon the principals of this city than to see that these afflicted children, who are backward or incorrigible because of some physical defect, should receive some help. It is the duty of the principal and the teacher to see that the defect is discovered and remedied. Of course, you know that when the defect is discovered you have no means of remedy; but give no peace to the parents of the child until the defect is remedied."

TREATMENT OF INEBRIETY.

WITHIN the past year renewed attention has been directed to the treatment of alcoholic inebriety through the publicity which has been given to the Foxboro, Mass., institution for dipsomania and allied conditions. It will be remembered that last winter and spring a committee of the Governor's Council, of which Lieutenant-Governor Draper was chairman, investigated the affairs of the Foxboro state hospital on the basis of certain complaints which had been made by inmates. It was a gratification to the public to learn, after a painstaking investigation, that many of the charges were entirely unfounded, but it was also determined that the methods which had been employed were not such as to commend themselves to modern theories of treatment of the class of persons for whom the hospital was designed. The hospital idea had apparently been lost sight of, and the institution had become rather a house of restraint.

In view of all the facts, and recognizing fully the conscientious service rendered by the previous board of trustees, Governor Guild has, nevertheless, seen fit to request the resignation of this board and to appoint another composed in part, at least, of persons who have given the subject of inebriety special study from a sociological as well as medical standpoint. The board, the composition of which is given in another column, is in fact made up of men who have had training in social science, penology, business, medicine and the law, and as such must be regarded as exceptionally well fitted to cope with the difficult problem before it. The choice of Mr. Robert A. Woods as the chairman of the new board is a particularly happy one. Since his graduation from Amherst College in 1886, Mr. Woods has devoted himself to the study of social conditions, not only in this country but abroad. He is the author of an admirable book on "English Social Conditions," published in 1891, and since its opening in 1892, he has been in charge of the South End House in Boston, an institution which has flourished financially as well as a social venture under his administration. Mr. Woods' associates on the board are all men of wide experience in various walks of life, and there can be no question that the problem of inebriety and the possibility of its treatment will be approached in a judicial spirit and from many sides.

It is certainly in accord with modern tendencies to consider the abuse of alcohol as a disease rather than a crime. The difficulty of distinguishing between a natural human weakness, for which a man must be held responsible, and an abnormal physical and mental state over which he has no control is naturally one of the utmost delicacy and one which involves many considerations which extend quite beyond the individual. The experiment, if such it may be called, which is about to be inaugurated at Foxboro, will be watched with great interest by penologists and physicians as well as by the great bulk of the people who regard social movements purely from a utilitarian standpoint.

MEDICAL NOTES.

DEATHS IN THE ALPS. — The number of victims by accident in the Alps is said to be greater this year than ever before. Eighty persons have been killed and 22 injured in 90 accidents, whereas, 76 were killed last year in 71 accidents. It is interesting to note that of the 80 persons killed 38 were guides.

President International Dermatological Association. — At the Sixth International Dermatological Congress, held at the Academy of Medicine, New York City, Sept. 9–14, 1907, Prof. Thomas De Amicis, of Naples, Italy, was elected president of the next congress, which is to be held in Rome, in 1910.

Death of Dr. Gaylord Parsons Clark. — Gaylord Parsons Clark, A.M., M.D., Dean of the College of Medicine of Syracuse University and Professor of Physiology, died at his home in Syracuse, Sept. 1, 1907. On the day after registration, at the opening of the college, a meeting of students and faculty will be held, at which recognition of Dean Clark's long and efficient service will be made by the chancellor and others.

Award of the Kingsley Medal. — The Liverpool School for the Study of Tropical Diseases has awarded the Mary Kingsley medal to Dr. Charles Finlay, chief sanitary officer of Cuba, the discoverer of the transmission of yellow fever by the mosquito; to Col. W. C. Gorgas who, in 1902, as chief sanitary officer at Havana, made practically useful the discoveries of Dr. Finlay; and to Dr. Theobald Smith, professor of comparative pathology in Harvard University, for his investigations on the blood parasite of the so-called Texas cattle fever.

boston and new england.

Acute Infectious Diseases in Boston. — For the week ending at noon, Sept. 18, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 25, scarlatina 37, typhoid fever 24, measles 10, tuberculosis 61, smallpox 0.

The death-rate of the reported deaths for the week ending Sept. 18, 1907, was 17.29.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Sept. 14, 1907, was 201, against 219 the corresponding week of last year, showing a decrease of 18 deaths and making the death-rate for the week 17.20. Of this number 107 were males and 94 were females; 197 were white and 4 colored; 134 were born in the United States, 64 in foreign countries and 3 unknown; 40 were of American parentage, 143 of foreign parentage and 18 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 16 cases and 2 deaths; scarlatina, 28 cases and 0 deaths; typhoid fever, 32 cases and 2 deaths; measles, 13 cases and 2 deaths; tuberculosis, 48 cases and 21 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 12, whooping cough 0, heart disease 18, bronchitis 2 and marasmus 13. There were 14 deaths from violent causes. The number of children who died under one year was 70; the number under five years, 83. The number of persons who died over sixty years of age was 26. The deaths in public institutions were 75.

There was 2 cases and 1 death reported from cerebrospinal meningitis during the week.

Typhoid Fever in a Gypsy Camp. — It is reported that the Boston Board of Health has ordered a camp of gypsies who have been in Dedham, Mass., for the past month to move, since typhoid has appeared among them. The camp numbers 150 men, women and children, and up to this time one death has occurred.

American Electro-Therapeutic Association. — The seventeenth annual meeting of the American Electro-Therapeutic Association is being held in Boston this week. The object of this association is to discuss the therapeutic bearings of electricity and to advance the general cause of rational electro-therapeutics.

Closing of the Boston Floating Hospital Season. — The Boston Floating Hospital concluded its work for the summer on Sept. 14, the boat having been in commission for seventy-five days. During the summer 366 babies have been treated in the permanent wards; in the day wards 555 have been received. The award of diplomas to the nurses and other suitable exercises closed a profitable season.

Out-Door Camp for Treatmtnt of Tuberculosis. — An excellent report is given of the patients who have been treated at the day camp for tuberculosis in Mattapan. One hundred and fifty-seven patients have been enrolled during the summer, and of these three fifths have gained, one fifth have lost ground, and the other fifth did not remain long enough under observation to determine results. In general, the plan of treatment by means of a day camp has again proved a decided success.

Vaccination in Rockland, Mass. — The school authorities in Rockland are finding difficulty in enforcing the vaccination law in the schools. Opposition is being made by parents of pupils, and the objections have become so definite that a test

case will probably be made in the case of a pupil refusing vaccination who was dismissed by the teacher, but declined to leave school. It appears that certificates have been issued to various pupils by a certain physician of Boston who takes the ground that no child is a fit subject for vaccination. Refusal to accept these evidently biased certificates is one of the chief reasons for the existing difficulty.

DEATH FROM CHLOROFORM. — A recent suit against a physician of Plymouth, N. H., for alleged malpractice in causing the death of a patient through the use of chloroform has resulted in a verdict for the plaintiff. The circumstances under which the chloroform was administered was a surgical emergency in the case of a young boy, a practice which it was maintained by the defendant's attorney was entirely legitimate. In spite of an able argument, supported by expert testimony, a verdict was returned against the physician. It would be interesting to know what the judgment of a jury would have been in England under the same conditions, where chloroform is the anesthetic usually employed.

BOARD OF TRUSTEES OF FOXBORO, MASS., HOSPITAL. — The following men have been appointed trustees of the Foxboro Hospital for Dipsomaniacs: Robert A. Woods, of Boston, chairman, head of the South End House in Boston, and an active worker for the betterment of social conditions; Frank L. Locke, of Malden, Mass., president of the Young Men's Christian Union of Boston, and formerly inspector-general on the late Governor Wolcott's Staff; Edwin Mulready, of Rockland, Mass., probation officer of the Superior Court for the counties of Norfolk and Plymouth; Dr. T. J. Foley, of Worcester, a practising physician for upwards of ten years; Dr. William H. Prescott, of Boston, who has from time to time held various positions in the Harvard Medical School and in connection with city institutions; James H. Perkins, of Boston, vice-president of the American Trust Company, and W. Rodman Peabody, of Cambridge and Boston, a lawyer of distinction.

NEW YORK.

SELLING OF COCAINE, A FELONY. — Among the bills passed by the recent Legislature and signed by the Governor, which went into effect on Sept. 1, was one making it a felony to sell cocaine, or any preparation containing it, except upon the written prescription of a duly registered physician, and another making it a felony for any druggist to sell a substitute when a special article is called for.

PRECAUTIONS AGAINST CHOLERA. — Dr. Doty, Health Officer of the Port, is taking special precautions with vessels arriving from Russia, owing to reports of the presence of Asiatic cholera in the vicinity of Libau. The Russian liner *Lituania*, which came in on Sept. 13, from Libau and Rotterdam, was detained at quarantine for twenty-four hours, and a thorough inspection made of all her passengers and crew.

INTERNATIONAL DERMATOLOGICAL CONGRESS. — The Sixth International Dermatological Congress was very successful, and the daily sessions, held in Hosack Hall, at the New York Academy of Medicine, which was tastefully draped with the flags of different nations, were well attended. During the week a number of entertainments were given in honor of the members. Large evening receptions were held by Dr. James C. White, the president, and by Dr. and Mrs. L. Duncan Bulkley, and on the night before the congress adjourned there was a dinner at the Waldorf-Astoria.

UNEXPLAINED OUTBREAK OF TYPHOID FEVER AT GOUVERNEUR HOSPITAL. — An unexplained outbreak of typhoid fever has occurred among the nurses and attendants at Gouverneur Hospital. Seven of the nurses were attacked almost simultaneously with the disease, and besides them the housekeeper and a woman clerk who took their meals at the same table as the nurses, while none of the patients in the hospital contracted it. Dr. Armstrong, the superintendent of Bellevue, and the others of the system of public hospitals to which the Gouverneur belongs, at once requested Dr. Charles Norris, director of the hospital laboratory, to make an investigation to discover, if possible, the source of infection. Before this was undertaken, however, Dr. Armstrong himself made a thorough examination of the buildings and found that there were no sanitary defects to account for the outbreak, a conclusion which was concurred in by the inspectors of the Health Department. Dr. Norris has as yet been unable to trace the cause of the trouble, but regards it as probable that, since only persons eating at the nurses' table were attacked, those affected got the typhoid germs from some uncooked vegetable such as lettuce or radishes. All the nine patients are reported to be progressing favorably, and the

places of the sick nurses have been supplied from the training school on Blackwell's Island.

Mortality in August. — The weekly reports of the Health Department show that during the month of August the mortality in the city represented an annual death-rate of 20.12, as against 18.71 in July and 18.79 in August, 1906. Among the diseases in which there was a decline in fatality were the following: The weekly average of deaths from measles decreased from 27.75 in July to 15 in August; the weekly average from scarlet fever, from 17.75 to 4.25; from diphtheria and croup, from 32.25 to 21.75; from pulmonary tuberculosis, from 150.25 to 148; from organic heart diseases, from 117.5 to 114; and from cirrhosis of the liver, from 23.5 to 17.5. Among the diseases which showed an augmented mortality were the following: The weekly average of deaths from malarial fevers increased from 1.75 to 2.5; from typhoid fever, from 10.5 to 16; from whooping-cough, from 7.25 to 16.25; from pneumonia, from 43.75 to 52; from bronchopneumonia, from 77.25 to 89.25; from diarrheal diseases, from 323.75 to 410; from diarrheals under five years of age, from 313.75 to 383.25; and from cancer, from 58.5 to 64.75. The increased death-rate, as compared with that in August, 1906, is largely due to the increase in diarrheal diseases in infants and young children; but as the past summer has been for the most part a cool one, it is somewhat difficult to account for this increased diarrheal mortality, especially as all the agencies for the saving of infant life have been in operation perhaps more comprehensively than in any previous season. The high point for the year in the deaths from diarrheal diseases in children under five years of age occurred in the week ending Aug. 3, when these amounted to 548, while in the corresponding week of last year there were only 342 deaths from this cause. For the first time in any month of the present year no deaths from influenza were reported during August.

Obituary.

FRANCIS HARTMAN MARKOE, M.D.

Dr. Francis Hartman Markoe, one of the prominent surgeons of New York, died after an extended illness, on Sept. 13, in the fifty-second year of his age. He was a son of the late Dr. Thomas Markoe, for many years professor of surgery in the College of Physicians and Surgeons, and a distinguished practitioner in this department of medicine. He was born in New York on March 20, 1856, and was graduated from Princeton University in 1876. Three years later he received the degree of M.D. from the College of Physicians and Surgeons, New York. From 1880 to 1884 he served as assistant demonstrator in anatomy in this school, and in the three following years as demonstrator. He was then made clinical lecturer in surgery, and from 1900 had been professor of clinical surgery. Dr. Markoe was attending surgeon to the New York and St. Luke's hospitals and consulting surgeon to the New York Orthopedic Dispensary and Hospital. He was more particularly identified with St. Luke's, with which he had been connected since 1889, and at the time of his death he was dean of the surgical staff of that hospital. He was also a surgeon of the New York Fire Department, and was held in the highest esteem by the officials of that department, as well as beloved by the rank and file, for the skill and devoted attention with which he cared for injured men. Not the least of Dr. Markoe's many fine qualities were his modesty and genial sociability. He was a member of many societies and clubs, and a charter member of the Medical Association of the Greater City of New York. His only brother is Dr. James W. Markoe, the obstetrician, who is the leading surgeon of the New York Lying-In Hospital.

6. Bardes says that tuberculosis of the middle ear is quite frequent, both in children and in adults. It is easily mistaken for an ordinary suppuration. In fully 65% of the children who have running ears the disease is tuberculous. Extensive destruction goes on without much pain and with few symptoms. The drum becomes ruptured and the cavity is thus drained. Often there is a fistulous opening behind the ear. The wound is unhealthy, sluggish and slow to heal. The infection occurs generally through the Eustachian tube and not by way of the external ear. It occurs when the fat pad over the mouth of the tube has been absorbed by the tuberculous process, and blowing the nose has allowed pus to be forced into the ear. Tubercle bacilli are not easily found in the discharge, being masked by the pus. Aural polyps and large granulations are rarely seen. The disease comes on insidiously, with loss of hearing and fullness in the head. In adults it is always secondary to tuberculosis in some other location. The drumhead is of a cheesy color, with numerous perforations. Much bone may be denuded. Treatment consists in general hygienic measures and stimulation of the tissues, with as little irrigation as possible.

2. Cabot classifies the important types of anemia as follows: (1) Chlorosis; (2) pernicious anemia; (3) secondary anemia, under which come (*a*) parasitic types; (*b*) other types, such as cancer, nephritis, etc.; (4) myelophthisic anemia, a name given to anemias resulting from leukemic overgrowth of white cells in the bone marrow and causing pressure atrophy of the red cell-forming tissue of the marrow; (5) aplastic anemia, which is very rare, occurring in young girls and accompanied by purpura. The blood is like pernicious anemia, except the red cells are smaller and rarely contain nuclei. Autopsies show yellow bone marrow.

Cabot thinks that no type of anemia can be positively diagnosed by the blood examination alone. Pernicious anemia, however, can be thus recognized occasionally. The most important single fact in the blood examination of this disease is the great reduction of red corpuscles, with a relative increase in the amount of hemoglobin. It is the large cell type of anemia. The other forms of anemia belong to the small cell type and are distinguished only by etiologic factors.

3. Meltzer finds recent advance in the treatment of anemia along three lines: 1. The direct transfusion method of Crile, which is so successful in experimental acute hemorrhages and is being used with good results clinically. 2. The development of the treatment of pernicious anemia, based on the possibility that this disease is caused by an anaërobic bacillus of the intestine. Herter, who discovered the presence of this bacillus in pernicious anemia, recommends colon irrigations. 3. Inorganic iron is just as capable of being absorbed and assimilated as are the organic iron compounds of the food.

5. Steele finds that diet is the most important factor in determining the amount of bacteria in feces. Foods that are easily digested and well absorbed leave little residue and nearly always have a low bacterial count. In uncomplicated constipation, usually spoken of as atonic, fecal bacteria are decreased. This decrease of bacteria may be the causal agent. In other cases of constipation, and in cases where there is excessive bacterial growth in the stomach, bacteria in the feces are increased. In normal persons it is found that only two so-called intestinal antiseptics, salicylic acid and bismuth salicylate, apparently diminish the fecal bacteria. The other so-called intestinal antiseptics seem to increase the intestinal flora.

7. Osborne advocates the treatment of uremia by: 1. Absolute muscle rest. 2. The withholding of all food, even milk; administering very little water by mouth, even if there is no edema, as the ability of the kidneys to excrete even water is often abolished. 3. Frequent colon irrigations of hot water, leaving some in the colon for absorption if the blood pressure is low and there is no edema. 4. The administration of thyroid. 5. Hot sponging of the skin. 6. Venesection in most cases, repeated if necessary, as it has been shown that an ounce of blood removes more toxins than eight or nine times that of fluid feces or than quarts of perspiration. 7. Nitroglycerin, if the pulse tension is high. [R. I. L.]

2. Battle maintains that there has been a real increase in appendicitis. He endeavors to find a cause. Grain now is generally ground between iron or steel rollers. Hence he suggests the possibility that small particles of

iron from these rollers may be the predisposing and sometimes the exciting cause of appendicitis. Concretions are often formed about such small particles. He relates numerous cases of small metallic bodies in the appendix. [R. I. L.]

2. Mendel shows that venesection, once so much abused, has been neglected for many years, and says that there are many conditions where it is of great value. The indications for using venesection are as follows: I. Disturbances in the corpuscles of the blood: (1) Poisoning by illuminating gas. It removes the poisonous compounds formed by the gas in the blood, which do not allow the CO_2 to be thrown off and lead to asphyxiation. (2) In uremia and eclampsia it gets rid of products of the toxic metabolism which are circulating in the blood. (3) In gout, during the acute attack, the author has used bloodletting with excellent results, the patients often remaining free from attacks for long periods after the blood-letting. The single attack always clears up more quickly with venesection than without. (4) In chloroses Mendel does not agree with certain other authors that venesection is of value. II. Disturbances of circulation: (1) In cerebral apoplexy the author recommends venesection in all cases, whether the blood pressure is high or not. He has used it in cerebral hemorrhage with good effect. (2) The author strongly recommends bleeding in all cases where the right heart is overloaded and dilated, as in valvular disease and myocarditis with broken compensation and acute dilatation; also in pneumonia where the right heart is overloaded.

4. Meissner reviews the routine methods of treatment in mercurial stomatitis and says that he has had moderate success with them. Of late he has used a new preparation, formamint, with great success. It is a combination of one molecule of lactose with five molecules of formaldehyde. Five or ten of these tablets are to be dissolved in the mouth during the day. He found it not only extremely efficacious in the cure of stomatitis, but also that patients who used these tablets from the start of the mercurial treatment never showed any tendency to contract a stomatitis. 4. Best enumerates the manifold symptoms of gastric ulcer, the only sure one being hemorrhage. The pain is always an uncertain factor, ranging from the slightest sensation of irritation in the stomach to paroxysms of intense pain. Tenderness on pressure, too, may be absent or entirely misleading. Many ulcers heal without symptoms or with the lightest manifestations, depending on the situation and depth of the ulcer. The slowest ulcer to heal and that most liable to give rise to symptoms is the pyloric, for the constant opening and closing of the pylorus during digestion gives little chance for healing. After partial or complete healing of an ulcer, a new set of disturbances may arise. At each irritation of the partially healed surface a spasm of the pylorus is set up. The stagnant food in the stomach further irritates the ulcer, causing a hypersecretion. These two factors in ever-increasing quantities cause the stomach to stretch, and may call forth fresh bleeding from the ulcer. This condition may clear up, spontaneously or under treatment, or it may stay latent for weeks or months. The stomach contents are colorless, cloudy, bile or blood-stained, usually containing small particles of carbohydrate food. The percentage of free HCl is usually increased, but may be below normal. A considerable tumor is often palpable over such a pylorus and may lead to error in diagnosis. Motor insufficiency and dilatation are the end results of this condition. Medical treatment often improves the condition but never results in a permanent cure, whereas the results of surgery in uncomplicated cases of pyloric stenosis and spasm of the pylorus have been most satisfactory. About half the author's cases of spasm of the pylorus were air swallowers, which makes treatment, both medical and surgical, much less likely to succeed.

5. In order that the early diagnosis of tuberculosis of the lungs by the tuberculin test be successful, every step in the routine should be most carefully carried out. The presence of fever is a contra-indication, and the test should not be applied in case of recent hemorrhage until four weeks after the bleeding. The patient must be put to bed and the temperature taken at two-hourly intervals, beginning at 6 A.M. the day before the injection is given. Ziegler recommends the rectal temperature. When sputum is present, the twenty-four-hour amount should be measured. A careful record of the condition of lungs, larynx, abdomen and urine should be made before the injection. The next day, at 9 A.M., 0.1 mgm. of Koch's old tuberculin is injected. If a rise of 0.5° C. in temperature is noted, the reaction is considered as positive. To confirm this a second injection of 0.1 mgm. tuberculin is given forty-eight hours later. If no reaction is noted, 0.4 mgm. is injected forty-eight hours after the first dose. The lungs should be watched for the appearance or increase in number of râles; the larynx for pain; the abdomen for tenderness on pressure over the kidneys or ileocecal region. This abdominal tenderness, however, may not be due to a tuberculous process. Pain and tenderness over the sternum are fairly common in a positive reaction, due, the author thinks, to local reaction in the intrathoracic lymph glands. Palpitation of the heart has been seen, due to local reaction in the glands of the neck, causing swelling and pressure on the vagus. Occasionally there occur extremely high temperatures, or the febrile period may be protracted four or five days. The usual length of the reaction period is twelve to twenty-four hours. The local reactions in lungs and elsewhere usually last from four to seven days. The author appends an account of his technique of preparing tuberculin for injection. [R. D.]

2. Schüffner, while in Sumatra, had opportunity to observe 129 cases of frambesia occurring in natives. In 81% of the cases he was able to confirm Castellani's observations, by finding the spirocheta pertennis in both smears from the skin lesions and in sections. The spirochetæ of syphilis and frambesia are very similar, but slight differences exist. The spirocheta pertennis is found in the rete Malpighi, in the necrotic tissue of miliary abscesses and along the lymph spaces; whereas the spirocheta pallida lies mostly along the course of the blood vessels in the perivascular tissues. The spirals numbered from 8 to 16. That the spirocheta pertennis is the etiological factor of frambesia the author thinks is undoubted, arguing from the likeness between syphilis and frambesia, which is very marked. Frambesia, though very closely allied to syphilis, is, however, a distinct condition. It is an infectious disease, beginning with a primary lesion, usually in a wound or excoriation. From four to twelve weeks later there comes a general papular eruption, the papules looking like raspberries when cleared of the surrounding crusts. Only rarely is a roseola present. The mucous membranes are never affected. Chronic periostitis is very common, especially in children. The treatment is anti-syphilitic, under which the condition rapidly clears up. [R. D.]

8. BOSSE, B. *The Present View of Lumbar Anesthesia.* (Concluded.)

1. Goldscheider thinks his method of light percussion gives extremely accurate information as to the heart borders. It has been proved by different observers to give borders in accordance with the x-ray pictures. He claims that the credit of applying this method to the heart belongs to him and not to Ewald, who used it on air-containing organs. If, instead of the finger as a plexmeter, a short glass cylinder with the end covered with rubber is used, greater sharpness in tone is obtained and more accurate borders can be outlined. Great care must be used to have the plexmeter parallel to the organ whose borders are being demonstrated.

2. Friedlander and v. Meyer describe a case in which, following a wound on the head, the tetanus involved only the muscles of the face on the side of the injury, with paralysis of the facial nerve on that side. Nineteen days after the injury the patient died, after developing spasm of the muscles of deglutition. There was at no time any involvement of the muscles of the extremities or back and only the slightest in those of the neck. The occurrence of local tetanus is explained with difficulty. Perhaps the tetanus toxin is carried to the spinal cord along the nerves which are adjacent to the point of infection, and there sets up at first an irritation only of those cells of the anterior horn, which are nearest the point of entrance of the poison. In human beings, however, especially in fatal cases, the poison appears usually to diffuse so rapidly that, as a rule, not local but general tetanus is a result. This case is interesting in the contrast between the intensity of the infection and its limited extension, involving only a few muscles, yet causing death in nineteen days.

6. Neuhauser reports that in Israel's clinic in Berlin, among 131 cases of nephrolithotomy, a threatening hemorrhage occurred 12 times or in 9%. The onset and course of these hemorrhages divide them into two types. First, those in which the bleeding begins with the operation and persists days and even weeks without being extreme, so that the patient gradually becomes exsanguinated. The second type is that of late bleeding. During an apparently uninterrupted recovery, suddenly an acute hemorrhage occurs from the operated kidney. Constitutional diatheses, as hemophilia, are the chief causes of the first type, while the origin of the second is often hard to find; dislodged thrombi in the renal vessels may, perhaps, explain some cases. Adrenalin, gelatin, ergotin, etc., alone are not of much use. In severe cases packing is the only treatment of avail.

7. Scherber concludes that all necrotic forms of stomatitis, however different their clinical picture, develop as bacterial infections upon some injury to the mucous membrane of the mouth. This diminishes the natural protective substances in the secretions, so that extensive and deep ulcerating and necrotic processes are formed. Painting with strong hydrogen peroxide, with a dilute mouth wash of the same, is the best treatment, its action being especially strong against the anaërobic bacteria.

8. KRAUS, F., AND NICOLAI, G. F. *The Electro-cardiogram in Pathologic and Normal Conditions.* (Concluded.)
9. BEITZKE, H. *A Review of Wright's Opsonin Theory.*

2. It is claimed that atoxyl is a powerful agent in the treatment of para-syphilitic conditions. Spielmeyer has given the drug a careful trial in sixteen cases of marked late syphilis and para-syphilitic conditions, without either improvement or arrest of the process. Given early, atoxyl might succeed in warding off such conditions. When the process is under way it is apparently useless.

5. Selig has tried the effect of the electric vibrator in many cases, cardiac and otherwise. In cases without cardiac lesion no diminution in the heart area was demonstrable. In all cases of heart disease with broken compensation, the orthodiagram showed a greater or lesser diminution in the size of the heart, with a slowing of the pulse and great relief of symptoms, due probably to stronger contractions of the heart muscle under the stimulus of the vibration. It is applied over the precordia or between the shoulder blades for between five and ten minutes daily. The author concludes that this method is a valuable adjunct to the treatment of organic disease of the heart.

6. Goldschmidt divides all asthma cases into three classes: (1) Acute or typical attack coming periodically and lasting a few hours. (2) Asthma chronica, wherein the patient has a series of recurrent attacks for three or four months at a time, followed by a period of absence of attacks. (3) Asthma permanens, wherein the patients have the asthmatic type of breathing for years without actual paroxysms, but are always very uncomfortable. In the first class the use of morphine subcutaneously is to be recommended, without danger of forming a habit. In the second and third kinds of cases morphine is of great value, and when rightly used causes no harmful results. It is to be administered in very small doses subcutaneously,

i. e., 2 to 5 mgm. ($\frac{1}{30}$ to $\frac{1}{13}$ gr.). Such small doses generally suffice to allay distress and are perfectly safe as long as no symptoms of morphinism appear. When, however, the original dose does not suffice to produce the desired effect, morphinism is present and the use of the drug must be abandoned.

7. Leuftleben has made many observations on a large series of cases of heat stroke, both mild and severe, at the maneuvers of the German army. These cases occur in healthy and strong young soldiers in whom all other diseases are ruled out by medical examination. They are, therefore, cases of uncomplicated heat stroke. The author found that the red cells of the blood showed a great loss of hemoglobin. Most of the protoplasm of the leucocytes was destroyed, the nuclei only being left in the stained specimen. The blood serum was always tinged yellow. Autopsies on the fatal cases showed an overloading of the venous circulation, especially heart, lungs and brain, with here and there ecchymoses of the serous surfaces. The blood is dark red and thrombi are found in the right heart and in the capillaries of the lungs and brain. The suddenness of these attacks and the conditions constant in the blood and at autopsy point to a rapid, severe intoxication. Experiments have shown that sudden removal of large amounts of blood from the tissues of animals causes a loss of the hemoglobin from the red cells. The hemoglobin circulating in the blood breaks up the leucocytes, setting free the fibrin ferment, leading to a clotting of blood in the capillaries and a damming of the blood into the venous circulation. The author carried out a series of experiments on rabbits by injections of fresh extracts of hemoglobin. The symptoms and post-mortem findings, as well as the blood conditions, corresponded almost exactly with those in heat stroke. After a comparison of these findings he concludes that heat stroke is an auto-intoxication due to a sudden pouring out of hemoglobin into the blood stream. In prophylaxis the author lays stress on the regular drinking of water by those who are taking violent exercise in the hot sun. Treatment of heat stroke should be subcutaneous injection of salt solution preceded by free bleeding, which should save lives except in the most marked cases. [R. D.]

11. LEXER. *Chondromata of Joints.*
12. EICHEL. *Dislocation of the Scaphoid Bone of the Foot.*
13. BLECHER. *Dislocation of All Three Cuneiform Bones.*

1. König discusses the various methods of preserving the shape and function of the lower jaw after removal of a portion of it. A temporary prosthetic apparatus is used, followed later, when the wound has healed, by a permanent one. The aid of a good dentist in adjusting the appliances is imperative. The experience of many of the German and Austrian clinics in this matter is given, the weight of opinions being in favor of the immediate India-rubber apparatus of Martin or the "inclined plane" contrivance of Sauer, followed later by a definite splint which can be removed and cleaned daily.

3. Vorschütz reports twelve cases in which areas of hyperesthesia of the scalp and neck accompanied injury to skull and brain. The presence of such zones indicates injury to the cranial contents. They are known to persist occasionally for two to three years after the injury and are thus of importance in forming an opinion for accident insurance companies. Such hyperalgetic areas are not usually present in cases of skull fracture with concussion, but are most often found in cases of gross cerebral contusion.

4. The results of four years' experience with anesthesia, in 3,082 operations at the clinic of Lexer, are reported. Ether, used in 1,806 operations, caused lung complications in 3.2%. Ether and chloroform (Billroth's mixture, etc.) used 744 times caused complications in 4.6%. Chloroform, used 532 times, gave the best figures, namely, 1.9%. Both local and lumbar anesthesia are also occasionally followed by lung complications.

6. During the removal of a large mixed tumor of the kidney capsule, Lexer was compelled to ligate and resect the inferior vena cava. Recovery took place without disturbance of the circulation, the child dying a half year later of recurrence. Draudt has found six similar cases in the literature. From these and from several series of experiments, it is shown that ligation of the cava, if it be done below the entrance of the renal veins, is seldom followed by any pathological disturbance other than transient edema of the extremities. Ligature above these veins is usually followed by death from renal disturbance through insufficient venous anastomoses.

8. Kudlek reports a case of giant-celled sarcoma of the patella which necessitated the removal of this bone. Two years later there were no signs of recurrence and the function of the joint was perfect.

9. Iselin reviews diaphragmatic wounds and herniæ. In every case of incised wound of the lower thoracic region one must consider the possibility of injury to the diaphragm. Prolapse of omentum through the wound confirms the diagnosis. Such wounds should always be sutured after access has been gained, either by enlarging the original opening or by resection of ribs. The resulting pneumothorax usually disappears in about eight days. Inflammatory lung complications are rare, and the pleural cavity can be closed without drainage in simple cases. If the reposition of prolapsed abdominal contents is difficult, the rent in the diaphragm should be enlarged. Through this opening the abdominal organs should be carefully inspected, and if found injured a laparotomy should also be done. Rupture of the diaphragm is about as frequent as are incised wounds. It occurs as a result of compression, either of thorax or abdomen, of a severity sufficient to alter the shape of the thorax or to increase the intra-abdominal pressure suddenly. Since liver, spleen, and kidney are frequently injured at the same time, approach by the abdominal route is the best. The diagnosis of a chronic hernia of the diaphragm containing stomach is usually possible. The x-ray is of great aid in this connection. The presence of large intestine in the hernia cannot be made out, as a rule, till laparotomy is done for intestinal obstruction.

10. The successful ligation of any of the large vessels of the lower half of the body is primarily dependent on the ability of the heart to overcome the sudden increase in blood pressure. Ligation of the aorta increases the pressure so greatly that, as a rule, the cardiac power is insufficient, and death ensues. Bilateral ligature of the common iliacs causes the same phenomena as that of the aorta. Unilateral ligature is only slightly dangerous, however, the blood pressure in the femoral returning to nearly normal in twenty-four hours. Bilateral closure of the internal iliacs, as also of the external iliacs extraperitoneally, is without danger. Ligation of the femoral artery is followed by gangrene of the leg in 60% of the cases. Closure of the femoral and of the external and internal iliac veins is harmless, as is also ligation of the cava below the renal veins. [W. C. Q.]

Experimental Cirrhosis of the Liver with a Tubercular Basis. STOERK (*Wien. klin. Wochenschr., No. 28*) finds that in guinea pigs infected with tuberculosis the liver shows very constantly cirrhotic changes which in mor-

phology resemble exactly the histological picture of human liver cirrhosis. The primary specific lesion starts in the acini in the portal vein ramifications, and from here extends into the neighboring peripheral parts of the parenchyma. Destructive and proliferative processes ocurring side by side are very characteristic, *i. e.*, destruction of liver cells synchronously with the formation of young connective tissue and regeneration in the biliary passages. Bartel, in an article in the same issue, finds results analogous to Stoerk's, viz., chronic inflammatory processes in other organs in the course of tubercular infections, which are characterized by a combination of regressive and progressive tissue changes. These changes are found most marked in the lymph glands and in the lungs. Jagie also, in the same number, reports a case of chronic tuberculosis of the left pleura and peritoneum in a woman forty-five years old, with macroscopic and microscopic beginning liver cirrhosis. This patient was not a drinker and was never jaundiced. [L. G. M.]

Miscellany.

TYPHOID FEVER EPIDEMIC AT NEW JERSEY STATE HOSPITAL.

THE following official statement has been made of the recent epidemic of typhoid fever at the state hospital, at Trenton, to the New Jersey State Board of Health:

Twenty-eight days have now elapsed since a new case of typhoid fever has been reported from the State Hospital, Trenton, and we may therefore conclude that the epidemic which recently prevailed in that institution has finally ceased.

To review briefly the important facts having relation to this outbreak it may be stated that the first case occurred April 8, 1907, in the person of an inmate of the hospital, located in the west wing of the building, who probably contracted the disease in the city of Trenton. Subsequent cases occurred in the same wing, and up to Aug. 13, 80 cases had appeared in the hospital with 16 deaths. All of these cases were located in the main build ng of the institution and no cases occurred in the Annex, notwithstanding that more than 400 of the inmates of the institution are cared for in that building. Twenty-three employees and other residents in dwellings on the hospital premises were affected with the disease. Investigations concerning the food supply, including milk and water, were negative, except that colon bacilli were found in the water of the spring from which a portion of the water provided for the hospital premises was obtained. Suspicion was at first directed to the water of this spring as the medium through which the infection was spread, but in the light of later developments it now appears improbable that the spring water had any influence whatever in conveying the infection, and we are led to the final conclusion that the disease was transmitted directly from patient to patient and through the agency of utensils and food infected within the building.

This conclusion is justified for the following reasons:

(1) The disease first appeared in the west wing of the main building and spread to other inmates in this wing, and as facilities were not provided for the isolation of convalescents the infection was communicable by them to other susceptible inmates.

(2) The spoons, forks, cups, etc., used in the dining rooms were washed by the insane inmates without boiling, and in the course of the epidemic every utensil in the building probably became infected, thereby exposing the food which entered the building to infection as soon as it was received.

(3) The filthy habits of many of the insane inmates of the hospital probably caused infected discharges to be generally distributed in the bathroom, upon the furniture, door knobs and other surfaces touched by the hands of the infected persons.

(4) From the west wing the infection was carried to other portions of the main building, but, as above stated, not a single case occurred in the Annex, indicating that the infection was not conveyed by milk or water, for the supply of both of these articles was from the same sources for both buildings. The water supply for all of the buildings on the hospital premises was taken from the same piping system, and in the standpipe, located near the Annex, the water which was pumped into the mains from the spring and from the wells was undoubtedly often thoroughly mixed before distribution to the various branches and service lines.

(5) Inquiry has shown that communication between the infected kitchens of the main building and the dwellings of employees, where cases of typhoid fever occurred, was frequent.

Correspondence.

LETTER FROM PARIS.

CALMETTE'S OPHTHALMO-REACTION TO TUBERCULIN.

[From our Special Correspondent.]

PARIS, Aug. 30, 1907.

Mr. Editor: During the past three months the vexed question of the value of tuberculin, as a means of *diagnosis* at least, appears to have taken a decided step in advance, — and this by the very simple process of the method's having been reduced from a general one, that affected the entire economy by the introduction of toxins into the blood circulation, to a purely *local* application without vascular effraction, by depositing the virus on a convenient and visible mucous membrane, the conjunctiva. It will be seen that the modification was not a very complicated one, — *mais encore, fallait-il y penser?*

The merit of this improvement is due to Calmette, of the Pasteur Institute of Lille, who has demonstrated that when one drop of a weak solution of tuberculin is introduced into the eye of a patient suffering from any tubercular process, medical or surgical, the conjunctiva reacts in such a characteristic way that the diagnosis of tuberculosis can be safely made, even when nothing of the sort had been suspected in the patient. You will observe at a glance that if his contention proves to be accurate, this is a step in advance in medicine of no minor importance. He calls it the *ophthalmo-reaction to tuberculin.*

I said that the tuberculin question "appears" to have made a great stride forward. For in matters of tuberculosis one can hardly be too circumspect: the subject is of such vast importance to the civilized races, to whom the tubercular processes are *the* enemy, and our hopes in this field have now been raised so many times by the laboratory men, their promises ultimately vanishing and leaving nothing but thin smoke and ashes behind them.

At the present moment, as regards this new test, we

are in the first heyday of our enthusiasm, and everything is *couleur de rose;* the dark side, which appears inevitable in every tableau, has not yet begun to show up. It is a French discovery, so the French have naturally taken it up vigorously and are investigating it on a large scale and as quickly as feasible. Its sponsors are first rate men, who leave nothing to be desired as regards reliability: Calmette, Letulle, Comby, Bazy, and others; and all of their accounts agree so far, so that in writing to you about it I hope that the reasons are adequate to warrant my suggesting that you should in your turn verify these results.

I need not take up the knotty question of tuberculin in general. It has been before the medical world for over fifteen years, has been the object of an almost incalculable amount of work and experimentation on the part of the very best of men; and yet it has so far resulted in what can fairly be claimed as little better than chaos, and a species of chaos that is particularly trying, a condition of affairs in which the seeker after guidance is utterly staggered by seeing good men, in whom he has equal confidence, asserting that a thing is at the same time both black and white, which cannot be.

Leaving all this uncertainty and disappointment aside, it will be seen that Calmette's idea is of a different order. He has taken one limited portion of the tuberculin question and made a definite assertion about it; it is one that can be readily tested by everybody, and we shall soon know beyond peradventure whether he is right or wrong.

Von Pirket, of Vienna, took the first step in bringing the use of tuberculin as a means of diagnosis down from a general to a local method, by proposing that instead of using it hypodermically it should be applied to a small scarified wound on the skin, when, if the patient were tubercular, the inoculation would be followed by marked local inflammatory reaction with the formation of a vesico-pustula, whereas if the patient were sound no reaction whatever would occur.

The veterinary surgeons Vallée and Arloing next observed that von Pirket's method holds equally good with animals.

This mode of procedure certainly seems preferable to the hypodermic one; but still, there is vascular effraction even here. Some of the tuberculin must be absorbed, and might give rise to disasters such as occurred with the original Koch's injection. Calmette's improvement, which is as follows, is evidently superior to von Pirket's, and would appear to be, so far as we now know, above criticism.

In order to avoid the irritating action of glycerin on the conjunctiva, Calmette uses only dry tuberculin precipated by alcohol (95%), sterilized by moist heat (not exceeding 105°), and dissolved in sterilized distilled water. The solution imployed is .01, freshly prepared, and strictly sterile. A good method is to prepare it extemporaneously by dissolving 5 mgm. of dry precipitated tuberculin in 10 drops of warm boiled water. With each patient, then, one drop is let fall into the inner angle of one eye, the lids being held apart to guard against any involuntary wink, which would eject the instillation at once. Patients must be cautioned not to rub the eye treated; and naturally the method must not be used in any eye already the seat of some disorder. This mode of procedure always suffices to produce the reaction in suitable conditions.

Five hours after the instillation, sometimes even in three, every tubercular patient shows very evident congestion of the palpebral conjunctiva, which becomes bright red, with more or less intense edema. The caruncula swells, reddens and is observed to be covered with a light fibrinous exudate.

This vascular injection increases progressively and is attended with epiphora. In six hours the fibrinous secretion has become more abundant, and collects in filaments in the lower conjunctival *cul-de-sac*.

The reaction attains its maximum in from six to ten hours. The patients feel no pain, only a little discomfort, with slight sensation of burning, and of deranged vision owing to the abundance of the exudate. There is no chemosis. Rectal temperature is not influenced. The patient's general condition and appetite remain excellent. The tubercular lesions are not modified in any way, the entire process being confined to the local area. It is easy to estimate the intensity of the reaction by comparison with the other eye.

The signs of congestion lessen and then disappear in eighteen hours with children, and in from twenty-four to thirty-six hours with adults. In no case has the instillation left any ill effects after it in the eye treated. When the test is to be repeated a second time, the other eye should be used, or else the original eye, but with a week's respite.

With healthy persons, and with persons suffering from non-tubercular complaints, this instillation of tuberculin between the lids produces no reaction, or at the most a slight redness at the end of one and a half to three hours, which soon disappears and is accompanied neither by fibrinous secretion nor by epiphora.

In some few cases the appearance of the reaction is retarded; it then begins in from twelve to twenty-four hours, and terminates in about seventy-two.

There appears to be no relation whatever between the intensity of the reaction and the gravity of the tubercular lesions. A discrete case of tubercular glands may give a more marked result than an extensive and advanced case of pulmonary trouble. The very few tubercular cases that have failed to react to this test have been patients on the point of death with whom all power of reaction was exhausted.

Comby has found that with children the .01 solution may produce an excessive reaction; he therefore advises in preference a solution of 1. to 200.

Such then are the details, as so far worked out, of this new and interesting test. Among them the following appear to be the most salient.

The simplicity of the method is all that could possibly be desired; it seems to be well within the powers of every practitioner, requiring no laboratory help of any kind. Furthermore its results are rapid; twenty-four hours suffice for a diagnosis. Its certainty, again, is claimed to be absolute. As regards this point, however, it will be well to remain on a prudent reserve; the idea of *certainty* seems rather to clash when used in relation to things medical.

Its innocuity has so far been found to be complete, as well in the case of children as with adults; neither in a general nor in a local sense has it produced any ill effects, although it has now been used in over 1,000 cases, and that is a figure that begins to count.

The fact must always be borne in mind that this test only acts when there are lesions *in process of evolution*, when some active focus exists; if then a patient fails to react, this does not mean that he never *has been* tubercular. One of its great services should be to show that a tubercular lesion is definitely cured.

But when the method will triumph will be in the *obscure* cases, and, above all, as a help toward an *early diagnosis!* and therein lies the key to success with these patients, as I need not tell *you!* If the method holds its promises, and enables the practitioner, struggling with a subjective diagnosis of incipient phthisis before objective disturbance is discernible, to affirm at the end of twenty-four hours and without possible risk of harm, "This is tuberculosis; the patient must resign present occupations and take to the hills," it seems difficult to overestimate the practical value of what will then prove to have been Calmette's idea of genius.

"Spectator."

"THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS FOR THE GENERAL PRACTITIONER."[1]

New York, Sept. 13, 1907.

Mr. Editor: I should have been more completely satisfied with Dr. Edward O. Otis's very instructive article if he had said even a few words in regard to the condition of the larynx in the earlier days of pulmonary tuberculosis.

Hyperesthesia, anemia, impaired movement of the vocal cords, tumefaction, and even ulceration of the larynx, will sometimes fix a diagnosis of pulmonary tuberculosis when physical signs in the lungs are negative, or doubtful. I take it that every general practitioner should know these facts.

Beverley Robinson, M.D

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED SEPT. 4, 1907.

WHITE, J. H., surgeon. Granted leave of absence for one month from Aug. 29, 1907. Sept. 4, 1907.

SWEET, E. A., assistant surgeon. Directed to proceed to El Paso, Tex., for special temporary duty, on completion of which to rejoin his station at Fort Stanton, N. Mex. Aug. 28, 1907.

ASHFORD, F. A., assistant surgeon. Granted leave of absence for seven days from Sept. 6, 1907. Sept. 4, 1907.

TAPPAN, J. W., acting assistant surgeon. Directed to proceed along Mexican border from Brownsville, Tex., to Nogales, Ariz., upon special temporary duty, upon completion of which to rejoin his station at El Paso, Tex. Aug. 28, 1907.

SEIDELL, A., technical assistant. Detailed to represent the Service at the fifty-fifth annual meeting of the American Pharmaceutical Association in New York City, Sept. 2–7, 1907. Aug. 30, 1907.

GOODMAN, F. S., pharmacist. Excused from duty for a period of ten days from Sept. 3, 1907, without pay. Aug. 31, 1907.

SCOTT, E. B., pharmacist. Relieved from duty at Norfolk, Va., and directed to report at the Bureau, Washington, D. C., for temporary duty. Aug. 31, 1907.

MEGAW, H., pharmacist. Directed to proceed to Vineyard Haven, Mass., for temporary duty, upon completion of which to rejoin station at Boston, Mass. Aug. 30, 1907.

CASUALTY.

Acting Assistant Surgeon A. C. Blain died at Brunswick, Ga., Aug. 28, 1907.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING SEPT. 14, 1907.

A. F. PRICE, medical director. Detached from duty as member of the Naval Retiring Board, Washington, D. C., and ordered to continue other duties.

F. M. GUNNELL, medical director. Retired, detached from duty as senior member of the Naval Examining and Medical Examining Boards, Washington, D. C., and ordered home.

T. D. MYERS, passed assistant surgeon. Retired, detached from duty in connection with the Naval Medical School, Washington, D. C., and ordered home.

A. M. FAUNTLEROY, passed assistant surgeon. Detached from the Naval Station, Tutuila, Samoa, and ordered to the Naval Hospital, Mare Island, Cal.

P. S. ROSSITER, passed assistant surgeon. Detached from the Naval Academy, and ordered to the Naval Station, Tutuila, Samoa.

F. P. W. HOUGH, acting assistant surgeon. Detached from the Naval Hospital, Annapolis, Md., and ordered to Washington, D. C., Sept. 16, 1907, for examination for appointment as assistant surgeon in the Navy, and then to wait orders.

J. C. CLAYTON, acting assistant surgeon. Appointed acting assistant surgeon from Sept. 5, 1907.

E. E. CURTIS, assistant surgeon. Detached from the Naval Hospital, Norfolk, Va., and ordered to the "Culgoa."

H. WELLS, medical director. Detached from command of the Naval Hospital, Boston, Mass., and granted sick leave for three months.

R. J. STRAETEN, assistant surgeon. Detached from the Naval Hospital, Mare Island, Cal., and ordered to instruction at the Naval Medical School, Washington, D. C., Sept. 30.

F. H. STIBBENS, assistant surgeon. Detached from the Naval Training Station, Newport, R. I., Sept. 22, and ordered to instruction at the Naval Medical School, Washington, D. C., Sept. 30.

APPOINTMENTS.

FRANK P. KNOWLTON, A.M., M.D., at present Associate Professor of Physiology in the College of Medicine, Syracuse University, has been advanced to the head of the Department of Physiology. A competent laboratory assistant to the Chair of Physiology will be selected at the earliest possible moment.

HAROLD DICKENSON SENIOR, M.B., F.R.C.S., at present an Associate in Anatomy at the Wistar Institute of Anatomy, Philadelphia, has been elected to the Chair of Anatomy and as Director of the Anatomical Laboratory at Syracuse University, to take the place formerly held by Dr. George M. Price. Dr. Senior was educated in England at Durham University. He was first Assistant Demonstrator of Anatomy at Durham University, then Junior Demonstrator of Anatomy at Charing Cross Hospital Medical School, London.

GUSTAVE M. MEYER, B.S., Sc.D., for four years Assistant to the Chair of Physiological Chemistry at Columbia University, New York, has been elected to the Chair of Physiological Chemistry in the Medical College of Syracuse University. Dr. Meyer received his degree of Sc.D., at the University of Geneva, Switzerland.

RECENT DEATHS.

CHARLES FRANKLIN BRAUCH, M.D., M.M.S.S., died in Amherst, Aug. 27, 1907, aged sixty-one years.

DR. LESTER S. HILL, of Providence, R. I., died recently as the result of an accident at the age of sixty-four. Dr. Hill was graduated from the Medical Department of New York University in 1872. At the time of his death he was assistant surgeon-general of the Rhode Island National Guard. His interest in military matters dated from the Civil War in which he had a brilliant record, finally being mustered out with the rank of colonel.

DR. SAMUEL LEWENGOOD, of New York, died suddenly on Sept. 10, at the age of forty-five years. He was graduated from Bellevue Hospital Medical College in 1882, and had spent all his professional life in New York City.

DR. JOHN H. SWASEY, of New York, died on Sept. 12, while visiting in Portland, Me., where his family came from. He was graduated from the College of Physicians and Surgeons, New York, in 1875, and devoted his attention largely to pathological studies.

DR. A. WARNER SHEPARD, of Brooklyn, N. Y., died suddenly from cardiac disease on Sept. 7, at his summer residence at Fort Hamilton, on the Narrows. He was seventy-five years of age, and was graduated from the Long Island College Hospital in 1886. For many years he was county physician of Kings County, and it is stated that he had the record of having performed more autopsies than any other physician in the State of New York. He was a native of Nashua, N. H.

LIBRARY

Address.

PULMONARY TUBERCULOSIS AND THE RÖNTGEN RAYS.*

BY PERCY BROWN, M.D., BOSTON,
Instructor in Rœntgenology, Graduate Department of Harvard Medical School.

WHO of us, after hearing Dr. Alleyne Adams's stimulating discourse before The Massachusetts Medical Society, a few weeks ago, did not leave his seat with a renewed and deepened sense of his responsibilities as a practitioner of medicine? That these responsibilities are imminent and immediate we felt intuitively, and they are devolved upon us as combatants in the great war which, as Dr. Adams said, is now before us.

In the midst of rumblings of internal strife in eastern Europe and the sight of thunderheads rising over the Pacific, our attention must not be diverted from this silent war — a war of far greater importance than any international contention, a war making wholly for good, a war in which lives are not to be lost, but saved. We are engaged in the strife, not as volunteers, but as conscripts drafted into service by the demands of progressive medicine, and he who fails to perform his share of duty must suffer from the stingings of conscience if not from open dishonor at the hands of his compeers.

The success of an army is dependent naturally upon the efficiency of its armament, and we fail of our purpose if we do not employ, of our own initiative, the arms given us to use. A powerful weapon Doctor Adams has described, to wit, the segregation of consumptives, and it is your duty, as clinicians, to make good use of it. Laennec and Koch are but two among many armorers who have contributed to our accoutrements, and it is to describe the use of the weapon furnished by another of these, Röntgen, that he who addresses you appears before you to-day.

The application of the Röntgen rays in the diagnosis of pulmonary conditions cannot be described as new, for as early as the year immediately following Röntgen's announcement, practical use of them was made for this purpose. Among European observers, Bouchard,[1] Bergonié,[2] Beclere,[3] Oudin;[4] and Fernet,[5] Levy-Dorn,[6] Loewenthal,[7] Grunmach,[8] and Holzknecht[9] published accounts of their work in 1897 or prior thereto. Above all, either in this country or Europe, stands the work of Williams,[10] of Boston, which possesses such accuracy in executive detail and such soundness of drawn conclusions that it will ever be a classic in the röntgenological field. Later, valuable additions were made by Claude[11] in France, by von Ziemssen and Rieder[12] in Germany, and by Pfahler[13] and Hickey[14] in this country. Rieder,[15] by introducing new refinements in technic, proved the skiagraphic record of diseased lungs a possibility. This possibility attained the dignity of a routine method through the efforts of Pfahler, of Philadelphia, with the augmentation of Hickey's later work on the apices.

* Address before the Worcester North District Medical Society, July 23, 1907.

The medical world, and to a certain extent the lay world, now understand that the optical action of the x-rays on physical substances results merely in a series of shadows, of varying density according to the resistance offered to the passage of the x-rays by the substance productive of the shadow. In no anatomical region is this shadow-complex more clearly depicted than in the thorax and its contents. Shadow impressions of many qualities are produced by the bony structures, the musculature of the heart and diaphragm, the great vessels and the lungs. The lungs themselves are penetrated by the x-rays with relative ease, and therefore they appear brilliantly illuminated — the brilliancy depending on the degree of inspiration, the thickness of the peripulmonic envelope, and certain natural characteristics of the individual in hand.

Mental impressions of two kinds are produced by observing these phenomena in a proper manner and may be described as two types: one type is an impression of the moving picture of respiration and its phenomena, or any abnormality connected with them; the other type is the impression produced by abnormal shadows of varying density, implying an inability on the part of the tissue in question to produce normal shadows. Upon these two types of impressions is based the matter of the recognition of intrathoracic disease by the x-rays.

An examination of the pulmonary region, properly pursued, may be divided into two procedures. One procedure consists in the visual perception of the shadow-complex as cast upon the fluorescent screen; on this screen we have portrayed, as in a *camera obscura*, not only the intrathoracic structures and their relations, but also their rhythmic movements: the expansion and contraction of the heart muscle, the bellying out and the shrinking in of the lung tissue and the rise and fall of the diaphragmatic dome. The other procedure results in the production of a permanent record by means of a process akin to photography, which may be termed röntgenography, of the intrathoracic viscera at the time the exposure to x-rays is made; this record is permanent, can be examined repeatedly at the pleasure of the observer, and can be compared with other records made at earlier or later periods in the course of the malady. Even such superficial mention of these two diagnostic procedures conjointly leads one naturally into an analytical comparison of them. Such comparison has been made by many authors, and an abridged repetitive statement at this time of the advantages possessed by both may be excused, perhaps, on the ground that the comparison may be used as a source from which to draw conclusions.

The value of fluoroscopic observations of normal physiologic movements has long been established by Cannon,[16] Hulst[17] and others in connection with the function of peristalsis. The stomach, particularly, has been watched, after the introduction of food, and has been found to undergo typical movements and to assume typical positions at various moments. Is it not, then, natural

to expect, as Williams did actually show, that fluoroscopy will reveal in the thorax also the physiologic undulations as concomitants of the function of respiration? It is thus easy to standardize normal chest movements, to form a basis upon which to judge abnormality. It has been found, for example, that the normal excursion of the diaphragm, as judged by the movements of its shadow on the fluorescent screen, is within certain constant limitations, depending, of course, upon the force and extent of respiration, and differing slightly on the right and left sides. The expansion of the lungs themselves may be carefully observed. As the lung becomes more and more inflated, it becomes less resistant to the passage of x-rays, and this fact alone plays an important part in one's power to recognize, not only an area already diseased, but a tendency to disease through deficient expansion. It is just as easy to standardize the position and movements of the heart in this way, as well as to discern any unusual appearance in connection with it, as is so often seen in pulmonary cases.

The remaining diagnostic agent of the Röntgen method is the photographic plate. What advantage has this, if any, over the screen, or does fluoroscopy, in its turn, have advantages not possessed by the plate? Williams said in 1901: "When instantaneous photography can be carried out in the lungs, a better opportunity will be offered for obtaining evidence of beginning pulmonary tuberculosis by the photograph than has hitherto been given." Our answer to this must be that we doubt that such time will ever come. Why? *Because there is no such thing as instantaneous photography*, and that there will be is the remotest sort of a possibility. Nevertheless, to the central idea of Doctor Williams's remark (to wit, that when we can obtain photographic results by exposures short enough to catch the lungs at rest, the plate method will become valuable), we are prepared definitely to answer. The routine exposure to x-rays necessary to obtain an impression of the adult thorax now is, or should be, sufficiently brief to be made easily while the patient holds his breath, either at inspiration, expiration or between the two.

It is partly on this account that examinations by röntgenography become valuable. They are valuable, also, from the fact that they furnish permanent records, to be examined at one's leisure, of existing abnormalities, and thus it becomes a simple matter to recognize a lesion which may have escaped the eye on the screen. The röntgenographic method furnishes, also, the possibility of making permanent records at various intervals in the progress of an individual's condition.

Many of my colleagues to the contrary notwithstanding, I am convinced that this method of examining a tuberculous chest cannot, to-day, supplant fluoroscopy for the following reasons:

(1) The diagnostic plate cannot show moving structures. In attempting to make a diagnosis of pulmonary tuberculosis from the degree of respiratory embarrassment, the essential is, not to observe the shadow of the diaphragm at the moment of the acme of its rise, or yet the profundity of its fall, but, rather, its rise and fall *in statu actionis*. The same is true of the pulmonary expansion; we can easily, in these days, make a röntgenograph at full inspiration, full expiration or at any *one* point in the respiratory excursion, but how, in this way, can we watch the *process* of respiration, or compare the right and left chests in motion?

(2) The diagnostic plate cannot offer another advantage which is presented by fluoroscopy — that by which the operator is empowered to increase or lessen, at his own pleasure, the penetrating strength of the Röntgen rays at his command, in the course of a single exposure. In the microscopy of urinary sediments, we are familiar with the fact that certain delicate and diaphanous tube-casts are best observed when the light from the reflector is diminished or tempered. Can you not conceive that the same necessity for holding the penetrating power of the Röntgen rays in abeyance may arise when a delicate infiltration of an apex, for instance, is to be demonstrated?

(3) The diagnostic plate can show but one aspect of the patient — any changes in position mean additional exposures. This is a difficult matter to overcome, as when the additional exposures are eventually made, many conditions, especially the degree of penetration of the x-rays, may have changed.

In order to look at the question with the greatest breadth of mind, we must consider certain qualifications of the röntgenograph not possessed by the screen:

(1) The screen cannot present its image permanently, and its images are of no value for purposes of record except as they form the bases for tracings, a matter later to be considered.

(2) The screen cannot so plainly convey its complete image on to the mind of the observer, although the deficiency may lie with the observer, no doubt. It is often hard for even a röntgenologist of experience to grasp, in the time usually occupied by a screen examination, all the points to be observed and noted. Subsequent examinations of the *same* shadow-complex are necessary, and Opportunity, in this as in other matters, knocks but once. On the other hand, the plate, produced at the time, forever repeats its story.

In the above disjointed manner, therefore, an attempt has been made to lay before you the *pros* and *cons* concerning the two great classifications of the Röntgen method of thoracic diagnosis. That these arguments for and against have many refinements and elaborations it seems hardly necessary to say. If one adheres too closely to the earlier method of fluoroscopy, he lays himself open to the criticism of being behind the times in Röntgen procedure; if, on the other hand, he be too quick to seize upon the röntgenographic method with its powers for brilliant results, he may be charged with erratic desertion of the old for the new. To all medical men who will give the matter sober thought, it must appear evident that each method has so many good points that it cannot be shaken from its place by the other.

The fluoroscopic method offers, to the trained observer at least, a greater chance for mental balancing and judgment. The röntgenographic method, on the other hand, appeals more to the clever technician as an opportunity to produce the brilliant results of his handiwork.

The fact is, gentlemen, we must accept both. We must accept the screen, because by that means we obtain a moving picture of living things obtainable in no other way. We must accept the plate also, just as, although we can feel the pulse at the radial artery, we are glad to accept a sphygmographic tracing of that pulse, or, although we can see the comet in the field of the telescope, we are glad to accept a detailed photograph of that comet and the surrounding solar system. Thus we find that the weapon we have received from Röntgen to use in this war on pulmonary tuberculosis is a double-edged sword. Although each edge cuts well, the weapon is most efficient when both are used.

It is necessary for us now to determine how much of an addition this weapon is to our armament, formidable though it seems to be. In other words, is the Röntgen method of diagnosis in pulmonary tuberculosis of value to us in the *early* cases? By early cases is here meant those cases which present no physical signs except, possibly, slight malaise with evening rise of temperature, a little loss of flesh, anemia and diminished appetite for food. It is in these cases that the most carefully conducted procedures of auscultation and percussion may offer little or no evidence. Without expectoration, it is most difficult to obtain the bacilli, and a Röntgen examination by means of the skiagraph offers no more satisfactory results than does the stethoscope. These are the cases pre-eminently for fluoroscopy. What such cases present on the screen has been so well described by Williams and others who have given the matter unbiased judgment, that repetition is not necessary. Suffice it to say that this fluoroscopic evidence is often characterized by a lessened rise and fall of the diaphragm, and a diminished expansion of the thoracic walls, even if we do not perceive, with the intensity of our x-rays under control, the unmistakable picture of a slight modification of the usual brilliancy of the lung area at one apex. A little practice will enable one keenly to observe these deficiencies, and even to measure the abnormality in centimeters.

Such cases may present to the trained ear the suspicion, for example, of prolonged transpiration on one side, or to the sensitive finger the slightest sense of resistance at one apex. This is undoubtedly true; but how often have cases been recorded where no such impressions have been conveyed to the most skilled finger or acute ear, and in which there has been found on the fluoroscopic screen the pulmonary expansion and the diaphragmatic excursion very nearly, but not quite, as full upon one side as upon the other?

When a positive diagnosis in an early case is somewhat doubtful, one would never question the convincing proof established by the presence of the bacillus tuberculosis in the sputum; nevertheless, we know that there does exist a prebacillary stage of the malady when to obtain the microorganism is a most difficult matter. There are also instances, as has been mentioned, where it is no small task to elicit signs by the stethoscope. In the face of such facts as these, it would be absurd, indeed, to claim infallibility for the Röntgen method, or for any other. All methods are useful when chosen carefully, and it is only when one is carried to extremes that the others are lost sight of.

In well-marked or late cases, where signs and symptoms are all too clearly evident by any mode of diagnosis, Röntgen examinations are valuable, chiefly as confirmatory evidence, in direct proportion to the value of any other one method. They are also directly useful in determining the *extent* of well-established disease, and the character of suspected lesions, such as cavity or calcified tubercle. In this way it is not usually more useful than other methods.

While it is my desire to avoid mention of technic as being outside the scope of this address, I wish merely to speak of one technical point. It is often desirable and advantageous to obtain tracings or outlines of fluoroscopic appearances as a means of rapid record or for teaching. This can be done by following the shadows on the screen with a pencil or other marker on celluloid or some transparent substance, in front of the screen. It is essentially desirable that the tracing apparatus be so arranged that the source of x-rays, which is behind the patient, may move with each movement of the pencil, in any direction. Thus it will be seen that the most direct x-rays will be always in a straight line from the pencil, and the element of distortion of shadow will necessarily be reduced to a minimum. This is the principle of so-called *orthodiagraphy*, which has been used, especially by the Germans, for some years. By thus outlining the application of tracings, I desire to correct the erroneous impression, created, possibly, by a previous remark, that no record can be obtained by fluoroscopy.

What is to be the future of this science, as applied to examinations of the chest? This is a question which we may well hesitate to answer, for who, in 1896, could have imagined that a permanent record of the thoracic contents on a photographic plate would eventually be made while the patient holds his breath? It is possible to conceive that our most radical advances may be exemplified by a combination of the röntgenograph and the cinematograph, or some other moving-picture device. Indeed, this has already been thought of seriously, and in a manner described. Only render it practicable, and the day will arrive when we may enjoy the altogether novel sensation of gazing at the enlarged images of our pulsating hearts and our expanding lungs projected through the stereopticon! As to the future none can say; the accomplishments of the past are marvels enough in themselves.

Conclusions which may be drawn reasonably from these observations are:

(1) That the Röntgen rays, through the media

of the screen and the photographic plate, are of distinct value in the diagnosis of pulmonary tuberculosis.

(2) That by virtue of the power given us by the Röntgen rays visually to perceive subtle changes in the thorax, we are often able to recognize the invasion of a pulmonary tuberculous process in an *earlier stage* of progress than it is to-day possible to do by the sense of hearing or touch.

(3) That to depend, however, upon the Röntgen method to the exclusion of others, namely, auscultation and percussion, the tuberculin test, or the staining fluids and the microscope, we do little else than proclaim ourselves bigots.

(4) That, if we recognize this new diagnostic agent, and make wise use of it, together with others already given us, employing *all* energetically for the benefit of the patient, while he is yet in a condition to be cured, we need never reproach ourselves with failure.

THE CHANNELS OF INFECTION IN TUBERCULOSIS, TOGETHER WITH SOME REMARKS ON THE OUTLOOK CONCERNING A SPECIFIC THERAPY.*

BY THEOBALD SMITH, M.D., BOSTON.

IN choosing this somewhat well-worn subject in answer to an invitation to speak on some aspect of the problem of tuberculosis, I was led by the present rather unusual activity in the study of the digestive tract as a portal of entry. This bustling activity is due in the first place to the somewhat morbid tendency of research to seek out the new, rare and unusual, and magnify and illuminate them so that to our dazzled eyes all the laboriously reared truths of the past become invisible for the time being. It is furthermore due to the dicta of two prominent men, one of whom proclaimed that bovine tuberculosis was of no consequence as a source of the human disease, and the other that all tuberculosis originates in infancy and that much of it was due to cow's milk.

The widespread movements tending towards the education of the public concerning the nature of tuberculosis and the modes of diffusion and transmission of the bacillus had brought to the foreground the older theories that tuberculosis is largely an inhalation disease and that the chief source of infection is the coughing consumptive. While all agree that the sputum is the vehicle in which bacilli leave the body, that there is, in fact, no other mode of excretion of the bacilli in man, which can be seriously entertained, there has developed a marked disagreement, or at least an attitude of assumed ignorance, as to the chief portal of entry. While inhalation has been and is still looked upon as the most frequently used mode of entry by some, others have gone so far as to deny the aërogenic infection of the lungs completely, and they trace pulmonary disease through the avenues of the intestinal mucosa and the associated lymph nodes, or the tonsils and cervical lymph nodes. In other words, the tendency on the part of a certain group headed by von Behring has been to cut out entirely the direct introduction of tubercle bacilli into the lungs through the respiratory tract and replace it with certain more circuitous routes, dealing with ingestion rather than inhalation.

Associated with and largely responsible for this change of view as to the significance of ingestion tuberculosis is cow's milk. Were it not for cow's milk as an occasional carrier of bovine tubercle bacilli we should probably have heard little of ingestion tuberculosis.

INGESTION AND INHALATION TUBERCULOSIS.

We have thus two main questions before us: 1. Is the path of the tubercle bacillus to the lungs chiefly by way of the digestive tract? 2. To what extent is bovine tuberculosis responsible for the human disease?

The difficulty encountered in taking a definite position on the question of the paths of the tubercle bacillus, both without and within the body, is due to the fact that almost anything we may say concerning the tubercle bacillus has a grain of truth in it, and may be realized at one time or another by observation and experiment. The goal towards which we should strive, however, is to discover the ordinary, common paths, and not the merely possible or extraordinary ones. Even in the experimental disease produced by tubercle bacilli in the lower animals we occasionally encounter peculiar localizations. The cryptogenetic tuberculosis of the bones, the kidneys and other organs, wholly outside of the usual paths of the tubercle bacillus in the body, shows well the occasionally irresponsible activities of this organism.

The character of the disease started by the tubercle bacillus, like that of other infectious diseases, is dependent upon a number of variable factors. Among the most important are: the virulence of the infecting organism, the age of the patient, the inherited susceptibility or predis-

* Read before The Massachusetts Medical Society, June 11, 1907.

position, a previous infection, accidents which convert a latent or healing local into a generalized disease, and finally the mode of entry.

As regards the virulence of the infecting organism, I must admit that our methods are not perfect enough to disclose minor differences. Until the facilities of the average laboratory extend to the breeding and rearing of our experimental animals, our tests upon animals can only be relied upon to distinguish such gross differences in virulence as exist between the bovine and the human type. There are, however, differences between cultures of the human type which impress themselves upon the investigator as more or less constant, although it would be difficult to define them readily. We may safely assume that a considerable number of slightly varying races of human tubercle bacilli exists, and it is probably not a matter of indifference to the patient which of them is at work.

Age is a most important factor, as all statistics and experimental inquiries show. In this respect tubercle bacilli do not differ materially from other infectious agents which find their easiest prey among the young. Statistics prove that tuberculosis becomes rapidly generalized in infancy and that it is a highly fatal disease. The conception of latency which has been introduced into the subject in recent years by von Behring does not at all tally with such statistical and pathological researches. That a bacillus which is especially virulent for the young should lie fallow in some organ or tissue of the body without multiplying is, to say at least, revolutionary to our current conceptions. Experimenters have been for years familiar with this conception of latency, or persistence, of infectious agents in the body of those who are relatively immune, and of those who have recovered from a disease, but not with the idea that bacilli can be latent in the highly susceptible young. It is possible that such bacilli may be very feebly infectious, and that subsequent disease is not due to them, but to later infection with more virulent types. It is furthermore possible that certain antibodies may be transmitted from mother to child, and that these are slowly excreted and disappear after three or four months unless the mother's milk continues to supply them. Under such conditions it is conceivable that, in the earliest months of life, or even longer, during the period of lactation, bacilli may be restrained and then multiply subsequently.[1] In any case I doubt that such latency could be prolonged over a year at the longest. The subject is a difficult one at best. How we can tell in any case that there has been no fresh infection where we suppose the disease to have been latent, I do not see. The possibility of fresh infection with, perhaps, more virulent material must always be reckoned with.

The influence of inherited predisposition, though an unknown quantity, cannot be given up at present, and I believe it plays an important part in the fight with tuberculosis. The capacity for producing antibodies, for phagocytosis and the other protective factors probably varies from individual to individual, and has its definite, prescribed limits.

The influence of one attack of tuberculosis, provided structures have not been seriously damaged, must be considered a distinct asset, since we now know that immunization of cattle with human tubercle bacilli is possible.

The influence of accidents, such as trauma, intercurrent diseases, secondary infections in favoring dissemination of the disease, is so well known that I merely mention them.

With all these factors at work and influencing the process, it is obvious that our inferences and conclusions as regards portals of entry, dissemination and the results of different kinds of treatment must be cautiously made, for they cannot safely rest on a few in part faulty experiments, which may strain and largely overpower the physiological protective mechanisms, and which may fail to reproduce the usual conditions present during spontaneous infection, but they must also take into consideration the work of pathological anatomy and histology, and utilize the results of statistics collected at the autopsy table.

Coming to the first controverted question, whether all tuberculosis is chiefly or exclusively alimentary in origin as maintained by some to-day we find that two different lines of research are involved in it:

1. The anatomical and physiological problem of the absorption of tubercle bacilli, soot, etc., by the mucous membrane of the intestines and their conveyance to the lungs and thoracic lymph nodes without being stopped by the mesenteric nodes.

2. The behavior of the organism in the presence of tubercle bacilli in any of its tissues under the influence of different degrees of a specific resistance or immunity.

As regards the passage of bacilli through the mucosa of the intestine it may be said that some twenty years ago the opinion was quite general among pathologists that the tubercle bacillus produces a lesion at the point of entry. With the more exact and detailed study of tuberculosis in infants and children, and the disease in cattle, this position had to be gradually abandoned. To-day most authorities will admit that the tubercle bacillus may pass through mucous membranes without leaving any pathological traces of its passage, to settle down in the nearest lymph nodes.

How the bacilli gain an entrance into the lymph vessels of the mucosa, whether by the aid of normal, physiological processes, or through minute lesions, is not determined. Their next station would be the mesenteric lymph nodes. The original claim held by many to-day is that in the mesenteric lymph nodes the tubercle bacilli come to rest and multiply, producing distinct lesions. If they escape it is only after leaving the well known traces of their passage behind.

Within the past four or five years a further modification of the original position has been

[1] In a former paper I advanced another hypothesis to explain such latency of tubercle bacilli: The Parasitism of the Tubercle Bacillus, etc. Jour. Amer. Med. Asso., 1900.

adopted by some, namely, that tubercle bacilli may not only pass through mucous membranes, but also through the related lymph nodes and settle down and produce disease at a point quite distant from the point of entry, without leaving any intermediate traces of their passage. It is obvious that if they escape through the mesenteric lymph nodes their next stopping place would be the capillaries of the lungs and, as a result, we would have a primary tuberculosis of the lungs due to swallowing tubercle bacilli. That this is possible few pathologists will deny; but is it probable and is its occurrence of sufficient frequency and importance to permit the overthrow of the aërogenic infection in phthisis? Two lines of experiments have been made to prove this. Dogs have been fed tubercle bacilli in milk or other fatty foods, and the tubercle bacilli found in the thoracic duct some hours later. Cattle have been fed with tubercle bacilli with stomach tube and slight tuberculosis of the lungs produced. Animals have been fed with various finely divided powders, either with or without stomach tube, and the pigments found in the lungs. These various experiments, though plausible on the surface, do not, in my mind, prove the contention. The large number of bacilli introduced may have overpowered the usual protective agencies, there may have been aspiration into the air tubes following withdrawal of the stomach tube, and finally other investigators claim that if pigments are fed in the usual way and kept wet they are not found in the lungs subsequently.

Perhaps the most opposition has been aroused by the attempts to trace pulmonary anthracosis to the ingestion, rather than the inhalation of soot, a process firmly established by the exhaustive experiments of J. Arnold over twenty years ago. Without delaying over the experimental data, let me call attention to the fact that large amounts of fine particles are taken into the digestive tract by our domestic animals daily in their food, and if any absorption takes place it would be detected. The mesenteric and meso-colic lymph nodes of the omnivorous dirt-eating pig are free from pigment. In the ox, the mesenteric lymph nodes of the young are quite free from any pigment, but when the milk diet has been replaced by the usual diet of grass, hay and grain, these nodes become heavily pigmented, not with soot, etc., but with pigment particles derived from the blood. When we turn to the thoracic lymph nodes in the same species draining the lungs, another picture presents itself. At first these nodes are unpigmented, but as the animal grows older a faint subcortical line of pigment shows itself which grows heavier and denser with age. This consists of black particles and translucent fragments. In the horse similar conditions prevail. A delicate black tracery of the subpleural lymphatics in old animals indicates a frequent deposit in the lungs as well.

It is of interest, furthermore, to note that in cows the primary foci of tuberculosis are situated in the thoracic lymph nodes among the pigment, suggesting most convincingly the aërogenic source of both. If this pigment in these nodes comes from the intestines, why does not some of it remain in the mesenteric nodes? Why do these, instead, retain in large numbers, chiefly in phagocytes, the blood pigment, and why is this not passed on? Possibly it may be answered that a special chemotactic affinity exists between the phagocytes on the one hand, and the blood pigment on the other, which does not exist between phagocytes and soot, etc. But if this answer is true, we surely cannot pass over the still more important chemotactic affinity between tubercle bacilli and the cells of the mesenteric lymph nodes.

A careful reading of the recent literature shows that the promoters of the theory that tubercle bacilli may readily pass from the intestines to the lungs without stopping to multiply, and thereby produce disturbances on the way, have not taken sufficiently into account the fact that tubercle bacilli are not like grains of lampblack, but living organisms which arouse a more or less prompt reaction on the part of the invading tissues, and which cannot travel about the body at will without being recognized and held.

The varying conditions of immunity and predisposition have much to do with the localization of tubercle bacilli and the shaping of the disease process. It is evident that the different stages in life do not react alike towards tuberculosis.

What may be true in earliest infancy is not absolutely so in childhood. Even puberty, middle life and old age have their respective types of tuberculosis from which, it is true, there are deviations, owing to the variable factors already mentioned, but there is as a rule a clearly defined growing immunity with age. There is even a varying immunity of the different organs of the same body towards the tubercle bacillus, and this may not be the same at different ages.

The lungs may be said to be the *locus minoris resistentiæ* for tuberculosis, not only for man, but for the higher mammals as well. Disease starting elsewhere, if not checked by death or recovery, sooner or later leads up to the lungs. In my second paper on bovine and human bacilli, published nine years ago, this behavior of tubercle bacilli was fully appreciated. It is there stated: "The question of phthisis as secondary to infection by way of the digestive organs is, however, one needing more attention. . . . In all mammals the lungs are evidently the most favored place of tubercle bacilli, and wherever the latter may be deposited, they sooner or later, unless the disease is checked, reach those organs, where the process spreads more rapidly than elsewhere."

In the attempt to establish the alimentary origin of tuberculosis, some have based their arguments on the fact that inoculation into different parts of the body, even into the tail, may lead to the pulmonary disease. This fact has been known for a long time, and has been mentioned by various observers. The question before us is not whether the lungs can be made diseased secondarily. That this is possible, and occurs frequently, as in miliary tuberculosis, is well known. The real question is whether the usual

types of pulmonary tuberculosis appearing at some one point in the lungs start from the intestines without leaving any signs of their passage or whether they are the result of inhalation. That is to say, Is the pathologist wholly powerless to trace the paths of the tubercle bacillus in the body? I think not. With the aid of our knowledge concerning immunity, the following general laws may be laid down:

In infants, the entry of tubercle bacilli is easier through all portals, and a generalized tuberculosis results from the rapid multiplication of bacilli and their diffusion through the feebly resistant tissues and vessels. With increasing age this indiscriminate passage of bacilli is checked, and the bacilli are held back by the reacting tissues in the nearest lymph nodes, the so called regional nodes. This gives us the common types of tuberculosis of childhood. It is also the type of the disease in young cattle. With increasing resistance, as at puberty and later, we have certain portals of entry, such as throat and intestines completely closed under ordinary conditions, and an inhalation disease appearing almost exclusively because the lungs, the most vulnerable organs, are still accessible through the respiratory passages.

COW'S MILK AND TUBERCULOSIS.

Closely interwoven with this new or revived doctrine of the alimentary origin of pulmonary tuberculosis is the widespread belief or assumption that milk infected with bovine bacilli plays a large part in the etiology of human tuberculosis. The history of this belief is of interest in showing the to-and-fro swing of medical doctrines. Following the epoch-making study of Koch in 1882, the assumed identity of bovine and human tuberculosis, as formulated by him, provided a basis for the world-wide movement against bovine tuberculosis as a source of the human disease. Excessive zeal in this direction was, however, kept in check by the scarcity of alimentary tuberculosis and the universally accepted doctrine that pulmonary phthisis was an inhalation disease.

In 1896 and 1898 I demonstrated the existence of two types of tubercle bacilli, the bovine and the human; emphasized the inadequacy of the evidence on which the transmissibility of bovine tuberculosis to man was founded, and pointed out that with the aid of these two types we could now build up more satisfactory statistics. In 1901 Koch, who had meanwhile studied the same subject, in a now memorable address, claimed that owing to the difference between human and bovine bacilli, bovine tuberculosis was a negligible factor in the human disease. As a result of this address, commissions were appointed in different countries to investigate Koch's claims. The German Commission reaffirmed the existence of the bovine and the human type, as representing distinct races of tubercle bacilli. The same has been done by the English Commission in their recent report. But the latter claim that these two types are simply extremes of an intermediate series of transition forms and admit, with considerable reserve, however, that there is some evidence of mutation, and that perhaps the bovine type may be converted into the human type by a sufficiently prolonged sojourn in the human body.

Coincident with this study of the relation of bovine and human tubercle bacilli to one another, nearly all observers who have studied series of cases of the human disease have found, in certain cases of tuberculosis, bacilli of the bovine type. The labors of Ravenel, the author, the German and English Commissions, Rabinowitsch, Fibiger and Jensen, and others have collected between 40 and 50 cases of the bovine type in infants and children. Some cases were fatal, others not. In practically all these cases the disease started either in the tonsils and related cervical lymph nodes, or in the mesenteric lymph nodes. So far as I know only one bovine culture has thus far been isolated from sputum, and this by the English Commission. Together with two other types it was isolated from a calf fed with large amounts of mixed sputum.

The cases from which these bovine bacilli were isolated are all selected cases, and we have at present no way of determining what percentage of progressive fatal tuberculosis is due to them. The statistics of alimentary tuberculosis vary from place to place, and even these cases are largely associated with the human bacillus. The only way to gain some adequate insight into the amount of damage done by bovine bacilli would be to take a series of consecutive cases both in sanatoria for adults, and in children's and infants' hospitals, and study the bacilli of every case for a given period. I venture the statement that probably not more than 1% of all cases will show bovine bacilli, and that in individuals over twelve years they will be found only very rarely. However, this is a mere guess and it should not take the place of actual figures.

The methods of isolating and identifying tubercle bacilli of the two types is now so far advanced that the clinical laboratories should take up this study. A series of cases carefully studied clinically as well as bacteriologically may lead to some means of clinical diagnosis between the two types of disease, since the bacteriological diagnosis under ordinary circumstances compels us to wait at least three months before a decision can be made. It is also highly desirable that any aberrant or peculiar type of tuberculosis be studied bacteriologically in order to determinine the nature of the invading bacilli.

The issue then would appear to be clear-cut and it would seem as if the whole question might be solved bacteriologically. But those who insist on the old doctrine of indiscriminate transmissibility of the two types of bacilli, and who are fortifying themselves by attempting to establish the doctrine of the general alimentary origin of tuberculosis, go a step farther, and assume that the bovine type may gradually change into the human type in the body, so that the adult phthisical patient would discharge the human type in

his sputum, whereas he may have absorbed the bovine type earlier in life through the digestive tract. This is, perhaps, a plainer and franker statement of the hypothesis than its adherents have been willing to make, but there can be no harm in viewing its bald outlines. The possibility of such a transformation I took into account as far back as 1898, and stated it as one of the theses to be investigated, although I did not then, nor do I now, believe in its realization.

The only way in which such an hypothesis could be tested would be to find a species of mammal in which the human type is always found, perhaps some race of monkey, and pass the bovine bacillus through a series of individuals. But the possibility of latent foci in such animals might at any moment imperil the accuracy of the experiment, by bringing into our cultures a human type from outside sources.

That the tubercle bacillus possesses a certain plasticity has been brought out by various investigations. Cultures from domestic animals other than bovines, but evidently derived from the latter, I have found slightly different as regards virulence from parallel bovine cultures. But that the bovine type should be converted into the human type has no analogy in the domain of bacteriology, and as long as it is not clearly proved to occur, it cannot be accepted on mere speculation. Again, if the bovine and the human cultures are indiscriminately transmissible to either species, why should two types have arisen? These must have been developed from some parent stock in obedience to the demands of the respective host harboring them.

Bacterial species producing specific invasive diseases in man and animals have their congeries of characters well fixed. Degeneration of such characters may occur, but the transformation of one into another, even closely related, race of variety has not been accomplished. Nocard claimed to have transformed mammalian into avian tubercle bacilli, but this solitary experiment should be repeated and tested with the aid of our present knowledge of the tubercle bacillus before it can be fully accepted.

The transmission of infectious animal plagues to man occurs in the case of glanders, anthrax, rabies and bubonic plague. In these infections which are due to bacteria, only one type of microbe is known, not two. The transmission of glanders to man occurs rarely when we consider the large number of glanders-infected horses in our midst, and the opportunity for infection. Man is predisposed only to a limited degree, and the transmission of infection requires, without doubt, certain specially favoring conditions, as seems to be the case in man when exposed to the bovine tubercle bacillus. If, as is claimed by some, the bovine and human types of tubercle bacilli simply represent a connected series, and if there is no sharp distinction, it is rather strange that adult man should harbor the least virulent type. Usually, the older the attacked individual the more virulent the attacking organism, for it is the old that infect the young.

To look towards another species for the main source of contagion in a human disease which has its own bacillus and machinery of transmission is a bacteriological anomaly, which has no parallel at present, not even in the bubonic plague. The anomaly is in fact so great that no experienced bacteriologist who has studied pathogenic species over any period of time is found to favor it. At the same time, I believe that we should not stop in our investigations, but work out the problem in every direction. If an anomaly is really discovered and proved, we must accept it. But I believe it wholly premature to base upon it far-reaching practical measures, whose cost to the community might destroy the opportunity of saving many times more lives than are injured or destroyed by bovine virus. In short, the entire field of bacteriology may be hunted over without avail to find a precedent for the assumption that two distinct races of bacilli adapted to two widely separated hosts, such as the ox and man, are indiscriminately transmissible. All that we can say is that in certain receptive stages in life, characterized by a low degree of resistance, such transmission may occur, and it does occur under circumstances not yet fully known. I am, therefore, of the opinion that man has only a limited susceptibility to bovine tuberculosis depending on certain still unknown factors. It is from this standpoint that I shall discuss very briefly the practical side of the subject.

The recent attempts to prove all tuberculosis of alimentary origin, if seriously entertained and if finally proved, would lead to a certain readjustment in our sanitary measures. The tuberculous patient would not only be dangerous near us, but at any distance, provided he came into any relations with us. Those who prepare our foods could infect us at any moment. The bread and pastry we buy, the milk we drink if handled by a tuberculous patient, even the clothes we wear would bring an element of danger. Every act of coughing would be dangerous, even if the sputum were carefully destroyed, because the spray might settle down and infect our food.

It seems to me that before placing an additional ban on the tuberculous we should patiently wait for satisfactory proof, and not be stamped from one position into another before we have inquired into the qualifications of the innovators, and the accuracy, if not reasonableness, of their statements. The problem of bovine tuberculosis should be dealt with in a similar temperate manner. We have learned during the past nine years that there is a bovine and a human type of the bacillus which all reliable bacteriologists have recognized. We have furthermore learned that in a selected number of cases of alimentary tuberculosis the bovine bacillus has been found. This is all we know and all the rest is uncertain and speculative.

As regards the source of the bacillus, we know that it may come from the udder or from the feces, when sufficient cleanliness is not observed. The udder becomes tuberculous through metastasis in, perhaps, 1% of tuberculous cows, roughly

speaking. The parenchyma or secreting structures become the seat of tubercles, and the milk may contain in certain cases large numbers of bacilli. When children are fed with such milk, they are overpowered by the many bacilli, and where a few might pass through, of the large numbers daily ingested, some invade the body. When udder tuberculosis exists in a herd samples of the mixed milk may prove infectious for guinea pigs, because the large numbers shed by one animal are disseminated through the entire mass, and enough may be present to make all the milk infectious for guinea pigs by inoculation.

There has been a vigorous discussion whether cows which simply react to tuberculin and which show no clinical signs of tuberculosis do or do not shed bacilli in the milk. Some observers contend that they may do so. Others deny the contention. My own experience coincides with the latter. Ostertag, who made a careful study of this subject for the Prussian government and who found no tubercle bacilli in the milk of reacting animals, pointed out that the discrepancies between observers may perhaps be explained by the soiling of the udder with feces. In cows with a discharging focus in the lungs, the swallowed sputum would maintain a slight infection of the feces. He drew the milk himself, and carefully cleansed the udder. In one case in which the feces were infectious, the udder when left uncleaned yielded milk which produced tuberculosis in guinea pigs. After due cleansing it failed to do so.

If Ostertag's interpretation is correct, and I am inclined to believe it is, a careful periodical inspection of dairies by competent and conscientious veterinarians, followed by the removal of clinically tuberculous animals, and all that had any suspicious abnormality of the udder, and the enforcing of cleanliness would eliminate practically all danger. Some chances for slight infection of the milk may still remain, as is equally true of typhoid fever, diphtheria and other infections in the dairy; but the amount of infection would be greatly reduced if not entirely eliminated, and in tuberculosis more than in any other disease, I believe that the number of bacteria plays a very important part in the final infection of the human subject.

THE RESTRICTION OF BOVINE TUBERCULOSIS.

In view of the relatively small percentage of cases of transmitted bovine tuberculosis, and the very slight chances for the infection of the milk of cows in the early stages of the disease, the question, what policy designed for the protection of the public will do the greatest good, is a perplexing one.

It seems to me that competent dairy inspection, the removal of all animals which show evidence of udder disease and which from a clinical examination can be pronounced tuberculous, and the enforcement of strict cleanliness are what should be insisted on.

This supervision, as I pointed out over ten years ago, not only greatly reduces the chances of tubercle bacilli in the milk, but it also restricts and suppresses two other factors which injure or destroy probably a hundred times more children than the bovine bacillus. These factors are miscellaneous putrefactive and fecal bacteria from filth, and the germs of specific human diseases accidentally introduced by those concerned in the production and distribution of milk.

About ten years ago the hope was entertained in some quarters that bovine tuberculosis might be completely exterminated by some concerted and persistent effort. While the attempt was in istelf laudable, it overlooked certain obvious facts, and it was planned on such a scale that it was bound to fail. It was based on the methods of procedure of the National Government in its fight against bovine pleuropneumonia and foot-and-mouth disease. The nature of these two diseases, their relation to other species, the character of the virus and its diffusion over a limited well-defined territory made the task of suppression a reasonably certain one, even though the cost was great. But bovine tuberculosis differs widely from these infectious diseases in almost every one of the details which have made the others manageable. To suppress bovine tuberculosis it will be necessary to have the co-operation, either compulsory or voluntary, of those who produce milk, and to establish, so to speak, islands or centers of tuberculosis-free animals, and slowly increase such territories. To look to our state and national governments for paternalistic aid to control a disease with which the farmers are now well acquainted will not work even if it were just to the rest of the population. The only way to make any progress is for the consumers to insist on milk from inspected herds and pay the price necessary to keep them free from disease.

In our own state, the Board of Health inspects dairy herds and the Cattle Bureau removes, pays for and slaughters clinically diseased animals. It also tests all animals coming in from other states at the public expense. What is the cattle owner doing in response to this paternal assistance to restrict tuberculosis? If we examine the annual reports of the Chief of the Cattle Bureau, Dr. Austin Peters, we find that in 1900 there were condemned, killed and paid for by the state 1,423 head of manifestly tuberculous cattle; in 1901, 1,341 head; in 1902, 1,001 head; in 1903, 1,172 head; in 1904, 1,658 head; in 1905, 1,625 head, and in 1906, 1,202 head.

In other words, the state can buy as many clinically diseased cattle as it cares to appropriate money for. The cattle owner raises his tuberculous crop each year to be shouldered and paid for by public taxation. The only way to make any progress after these many years of patient compensation for diseased animals is for the state to take them without compensation, and for the public to patronize milk from tested herds. It has been amply shown that tuberculosis can be restricted if a little thought be given to the subject. Our national government distributes tuberculin and suitable directions for its administration,

free of charge. Surely the means for individual initiative are not lacking, excepting one, and that is a little judiciously applied coercion. A law to remove the item of compensation after a definite number of years would probably bring about the desired reform.

There can be no doubt that the public is in a difficult situation with reference to the milk supply. The congested population of our large cities must draw its stock from a very large territory, and few can trace to the herd the milk that is daily delivered, owing to the multiplication of middle men necessarily engaged in its distribution and the distance from which it is brought. The adjustment of this difficulty is a delicate one and is an interstate question. In the meantime, the helpless and distracted public may protect infants and young children from the occasional chances for infection by pasteurizing the milk. It should be stated in this connection that the lowest temperature which destroys tubercle bacilli is 140° F., and at this temperature the shortest allowable time is twenty minutes. The heating must be done in closed vessels to prevent the formation of a scum or film in which tubercle bacilli may survive the heat.

I wish finally to mention a possible source of infection to which no attention has been given. It is one which I mentioned as worthy of consideration in 1898. If the milk of tuberculous cows may infect children, may not the dust and dirt of cow stables affect adults working in them?

I have already stated that only one not very clear case of bovine bacilli in sputum has been reported. It seems to me that the study of a series of cases of tuberculosis among those working in cow stables is desirable at the present time, and I am prepared to make such a study if the sputum is sent to me fairly fresh and a carefully prepared record of the history and present condition of the patient forwarded with it.

The conclusions which I think are warranted by the investigations upon human and bovine tuberculosis up to the present may be stated as follows:

1. The coughing consumptive is the chief source of infection.

2. The digestive tract is not the exclusive or even predominating portal of entry for pulmonary phthisis. It is highly probable that most cases are due to inhalation or aspiration.

3. In infants the bacilli probably gain entrance through all portals more easily than later in life, and the disease becomes more easily generalized. There are no rational grounds for believing that latency in infancy plays any appreciable rôle in the disease of later decades, but ingestion probably does play a much more important part in infantile tuberculosis, owing to habits and susceptibility of this period of life, than has been granted heretofore.

4. Bovine tubercle bacilli are found associated with a certain, at present not fully calculable, proportion of cases of abdominal and cervical lymph-node tuberculosis in infants and children.

5. There is at present no evidence that bovine bacilli may be transformed and assume the human type in the human body.

6. The discharge of tubercle bacilli into the milk of cows may take place abundantly in udder tuberculosis. In a small proportion of manifestly tuberculous cows without evidence of udder disease, it may take place at times in very small numbers.

7. A reasonable restriction of bovine tuberculosis below the danger limit to man is possible with the aid of tuberculin and segregation, and the removal of clinical cases and of udder disease. An eventually complete elimination can be brought about in this way in any herd, provided other domestic animals, such as pigs, cats and dogs, are kept under control as possible reintroducers of the infection.

8. The complete elimination of bovine tuberculosis may be hoped for in the distant future. An active co-operation of individuals with municipal, state and national forces, by exerting a steady pressure and diffusing more knowledge among farmers as to the nature of tuberculosis and the use of tuberculin, may lead to its final disappearance.

9. The factor of bovine tuberculosis in the human malady is not of such importance that it should be permitted to imperil the proper execution of measures designed to relieve and cure the strictly human disease, or divert attention from it as the chief evil.

THE OUTLOOK CONCERNING A SPECIFIC THERAPY IN TUBERCULOSIS, AS VIEWED FROM THE EXPERIMENTAL AND COMPARATIVE STANDPOINT.

Having been asked to say a few words upon the present status and promise of serum therapy and vaccine in tuberculosis, I do so somewhat reluctantly, and I place myself distinctly upon the experimental standpoint for two reasons. In the first place I have had no personal experience with the use of serums or vaccines as applied to cases of the disease. In the second place I believe that our fundamental data must come from experiments on animals.

Since the various kinds of treatment of tuberculosis may all be classed either as passive or active I shall group my discussion under these heads. It is now pretty generally understood that serum therapy is a method of transmitting one or more antibodies, produced in some animal artificially, to the patient in order temporarily to fill a gap, to provide a substance which is wanting but essential in the struggle against the disease. This want is filled by the serum until the body has sufficiently recovered to manufacture for itself the antibody. The use of serums is most successful in rapid toxic diseases in which there is only toxin to be disposed of, but no bacteria. When we come to the slower invasive diseases, like tuberculosis, the injection of a therapeutic serum would have to be made over long periods of time because its need would be continuous. But even then it is a question whether the serum would be of any permanent benefit, because to

throw off the disease the body must finally make its own antibodies. The serum is like a crutch which must sooner or later be given up when the patient is strong enough to try walking alone.

Approaching the subject from the practical side we know that no serums have proved to be of any generally recognized value in the treatment of invasive diseases. The immunization of large animals is slow and difficult, and it can be carried only to a certain point. Such sera would in any event be very expensive and hardly within the reach of the average patient. Then, again, the repeated injection of foreign serum over a long period is not to be looked upon lightly.

From both the experimental and the practical standpoint the outlook for serum therapy is not encouraging, though I should not wish to say that it is hopeless. In some one form or another, unknown to us at present, there may be built up from the fragments of the present passive and active forms of treatment a successful method accessible to all patients.

Owing to the difficulties, both theoretical and practical, surrounding the use of a curative serum, investigators have again turned to the method of inducing active immunity. This consists in stimulating and rousing the latent activities of the diseased body to produce its own antibodies. Begun with the introduction of the old tuberculin by Koch in 1891 it has had various fortunes, but it seems again fairly well established to-day. All the methods are based upon the introduction into the body of the products of tubercle bacilli. The fundamental underlying principle appears to be a reliance upon the diseased body itself with the understanding that it possesses sufficient forces to establish its own cure if these forces are properly husbanded and properly called forth. These forces are limited in amount at any given moment, and perhaps in time exhaustible. They should not be wasted because we know that the organism reacts with a very lavish production of antibodies. In the treated horse, for example, diphtheria antitoxin present in the blood can neutralize thousands of times the amount of toxin which is injected at any given time.

The presence of tuberculosis indicates that these antibodies are below normal, or have been so at some time in the past. These considerations suggest the use of very small doses of the stimuli and only at the proper time. Sir A. E. Wright maintains that in the antibodies known as the opsonins we have such a guide, and the index of this guide is phagocytosis. Some are inclined to neglect this guide, and utilize clinical symptoms in the treatment.

It follows from the theory of action of these stimulating substances that they are not called for in active, febrile stages, when the body is apparently fully roused and needs no stimulus from without. Under such conditions an antitoxic serum might be helpful to neutralize the over-abundance of toxins until the system had recovered itself.

It is furthermore evident that the application of these substances may bring into action various tissues of the body beside the immediate focus of disease. The whole body may thus be laid under contribution artificially to relieve a limited area, which is unable to protect itself.

In the practical development of this mode of treatment by gradual cautious stimulation, many substances have been used, all of them derived from the tubercle bacillus. The old tuberculin comes first in the order of time; next the new tuberculin, representing ground-up bacilli; then there are the watery extracts of tubercle bacilli used by Maragliano, the filtrates of the culture fluids as used by Denys, and lastly the mystical tulase of Behring. Whatever may be the perfection to which these methods of active immunization may be carried in the future, there still remains the unknown quantity of the capacity of the individual patient to produce the necessary antibodies and bactericidal forces. If these are lacking therapy is powerless to check the disease.

This discussion, brief though it be, has led up to three propositions:

1. Serum therapy is at best a temporary palliative method in infectious diseases which are long drawn out, and which must finally be met by the specific resources of the body itself.

2. The need of discriminating power on the part of the practising physician between individual and individual in the application of remedies which stimulate the production of antibodies. He is evidently not going to be eliminated by an advance in medical science. In fact, he must be better trained than ever, especially in the fundamental principles of immunity — a subject quite new but already rich in acquisitions, which may be called the physiology of the infectious diseases.

3. To each human being are given certain talents to husband and develop and not to squander, for therapy cannot add to them. It falls to the lot of the physician to discover during disease the size of those hidden talents, if he can, and to utilize and manipulate them in the best interests of his patient.

SEPARATE NURSING AND ISOLATION IN TYPHOID FEVER.

BY ELLIOTT P. JOSLIN, M.D.,
AND
CHARLES L. OVERLANDER, M.D.,
BOSTON.

In 1888 Dr. R. H. Fitz[1] demonstrated that typhoid fever was occasionally contracted in this vicinity by patients during their stay in a large hospital, as well as by nurses and other attendants, and he appended a list of directions for the prevention of future contagion, which received universal adoption. Yet cases of typhoid fever thus acquired continue to occur, and it is pertinent to inquire if there are not other practical, preventive measures which might advantageously be employed.

Exposure of patients. — Most private hospitals in this vicinity refuse to accept typhoid patients at all, while others do so only on the condition that the typhoid patient shall have one or more

[1] Fitz: Bost. Med. and Surg. Jour., 1888 vol. lxviii, p. 513.

special nurses. So far as we are aware there is no private hospital in Boston which allows a nurse to attend both typhoid and non-typhoid patients at the same time. Some physicians and more surgeons refuse absolutely to send their cases to a private hospital which receives those ill with typhoid fever, and others prefer that hospital which refuses to treat the disease. Yet all of us — physicians and surgeons alike — have urged patients to enter the large public hospitals, where we knew they would be placed in close contact with typhoid cases in open wards, and cared for by nurses who also had typhoid patients under their charge. Is it justifiable to expose a patient in a large public hospital to typhoid fever any more than in a small private institution? McCrae,[2] in his excellent monograph on typhoid fever, quotes Schuder in the statement that 3.3% of all cases are due to hospital infection. Statistics upon such a point are difficult to obtain, because the average stay of patients in hospitals is so short that the disease does not usually develop until after discharge. We have therefore made no attempt to pursue this aspect of the question. Two striking instances of infection are, however, well known to the writers.

Exposure of nurses. — Frequently nurses are exposed unnecessarily to typhoid fever in large hospitals. It is not uncommon for each of the nurses in a ward to have charge of one or more typhoid patients along with other cases. Thus, on one day recently in one of our larger institutions, twenty-three female nurses, fifteen male nurses and thirteen physicians shared in the care of twenty-eight typhoid patients. These same patients could easily have been gathered into two small wards. Nine nurses and three ward tenders would then have been amply sufficient for their care, and thus the exposure of fourteen nurses and twelve ward tenders would have been avoided. Is this not worth while? If all the typhoid cases in a ward were given to one or more nurses and the non-typhoid cases to the remaining nurses, even then the exposure of the nursing staff would be greatly reduced.

There is little more additional exposure in caring for four typhoid patients than in caring for one. The knowledge that she was a "typhoid nurse" would lead a nurse to redouble the precautions for her own self-protection. The question would not be constantly arising, Is this a typhoid patient? for all would be typhoids and precautions would be the rule of the day and not the readily forgotten exception.

A hospital nurse in Massachusetts is about eight times as liable to contract typhoid fever as the ordinary citizen.[3] During the years 1902–1906 inclusive, we have found that twenty-six nurses contracted typhoid while working in six hospitals. The average number of nurses employed each year in these hospitals was 322 and the total number of cases under their charge, 2,988. In other words, for each 114 cases of typhoid fever treated, one nurse came down with the disease. The typhoid morbidity rate for the nurses in these same hospitals was 161 per 10,000 living instead of 20 per 10,000 living, which is approximately the typhoid morbidity rate for the whole population of the state.

When one considers the danger which nurses now run, it is perfectly plain that, under no circumstances, should a "probationer" ever come in contact with a typhoid case. Further, typhoid nurses should never be overworked, and the greatest pains should be paid to the health of the night attendants.

Ward tenders are particularly prone to typhoid fever for several reasons. Their general education is often not as good as that of nurses, and less attention is paid to their medical training. Of a yearly average of ninety-four ward tenders in five hospitals, twelve contracted typhoid, making the incidence for the five years 252 per 10,000 living; or, in other words, they are nearly thirteen times as subject to the disease as the average citizen.

It cannot be raised as an argument against this plan of concentrated nursing of typhoid patients that the nurses will get insufficient training. That might hold for some hospitals in Germany, where there are few typhoid entries in a year, but not for hospitals in the State of Massachusetts, in which during 1905, 2,794 cases of typhoid fever were reported to the Board of Health. Nor is it in any respect harder to care for several typhoid cases at one time, than for both typhoid and non-typhoid cases. On the contrary, it is far simpler to do strictly typhoid or non-typhoid nursing. The typhoid utensils will all be found in one place, supplies will be made and procured in bulk, and thus many duplicate steps saved. The concentration plan of typhoid nursing for typhoid patients should easily lessen by one-half the number of days of a nurse's exposure to typhoid fever. In the hospital above mentioned it would reduce the exposure by two thirds.

Separate nursing for typhoid patients removes the chief danger to which the other patients are exposed. The "go betweens" are eliminated.

But all such measures are only a make-shift, if the typhoid patients remain scattered about the ward. They should be grouped in neighboring beds. It is true, as Edsall has pointed out, that one typhoid case may harm a fellow typhoid case, but the danger is far less than that of giving the disease to a neighbor weakened by some other disease. Of course, such separation will naturally lead to the giving up of one side or one end of a ward to typhoid cases, and eventually of the whole ward. The isolation of typhoid patients in hospitals, as well as in private houses, was made compulsory in Germany two years ago and the day is not far distant when the unnecessary exposure of patients and nurses to typhoid fever in the United States must cease.

[2] McCrae: Osler's "Modern Medicine," 1907, vol. ii, p. 83.

[3] At the meeting of the Association of American Physicians in Washington, May, 1907, Dr. D. L. Edsall read an instructive paper, not yet published, on typhoid contagion in hospital wards. In general, our data are similar to those he obtained for hospitals in Philadelphia.

THE QUESTION OF "JUSTIFIABLE HOMICIDE."

BY CHARLES GREENE CUMSTON, M.D., BOSTON.

THERE is hardly a day goes by that the daily papers do not give a detailed account of some crime arising from jealousy, and it would appear natural to suppose that on a question so frequently brought up, public opinion and penal science should have arrived at a solution no longer to be disputed. Such, however, is not the case, and there are few subjects in penal law which have been so frequently discussed and will continue to be.

In most cases of so-called "justifiable homicide," the jury will render a verdict of not guilty, and it is quite certain that they cannot be blamed. We have endeavored to discover the reason for this condition of affairs and also problems that "justifiable homicide" brings up. There are three prinicipal ones which deserve attention, the first two belonging to the responsibility of the criminal from passion, the third being the question of the application of the law. Firstly, as to responsibility; should one consider an individual, carried away by his passion, possessed of his mental faculties to their full extent? At the present time we no longer possess the beautiful serenity of our ancestors who divided man into healthy beings and lunatics, the first possessing all their intellectual faculties, especially a stronger will and a mind never clouded; the others, without will, simple machines, always depending upon the physician and never on the magistrate.

The progress of medicine and psychology has taught us that a perfect moral health in man is quite as rare as his perfect physical health. Even outside the realms of characterized pathologic conditions, it is very certain that the will is quite susceptible of a plus or a minus state; man's condition of health, and his nervous system in particular, has a sure influence over his degree of volition, as well as his force of will. If this fact is considered in relation to the other upheld by Gall, who says that in every passion is to be found the starting point of a monomania, one can readily understand how the problem of responsibility is to be put for the criminal from passion. A weak man may become dominated by a passion to such a point that it completely absorbs him and he merely lives for it. In the blindness that his jealousy causes, he wakes up one day to find all things "red," and he strikes.

Should the law take into consideration this intoxication from passion, this instantaneous insanity? The psychologic problem becomes complicated by a moral problem. If passion may thus deprive an individual of his will power to such an extent that he commits a crime, is it not the fault of this man? There was a time when passion had not taken complete possession and when the subject should have struggled against it, he did not on account of presumption and self-confidence. Like Faust, he was desirous of knowing a dangerous unknown, and should he not, like Goethe's hero, pay the price of the future? Should the law be held to appreciate this particular form of responsibility? — a responsibility rather more of a social than a moral one, and consequently quite distinct from that of other criminals. It can be readily understood how complicated the question may become as soon as there is the slightest doubt of the mental condition of the accused, as, for example,— the occurrence is extremely frequent, — when insanity is found in the antecedents of the subject. We here merely indicate the problem.

Another question which comes up, relative to the responsibility of a criminal from passion, is the following: if a person is animated by rage and hatred to such a point as to wish the death of the being that he formerly loved so dearly, the unfortunate outcome is not always entirely due to the criminal, nor to the loved one, but occasionally also to defects in legislation which insufficiently protect humanity. For example, a man having seduced a young girl renders her a mother, and, as soon as he learns of this unfortunate paternity, the seducer abandons his mistress. This is a frequent occurrence, and only too often it has as a consequence to force the unfortunate girl to crime, namely, abortion, suicide, or the murder of her seducer. Beside the responsibility of this woman who murders, which we do not dispute at all, a certain portion of the responsibility is incumbent upon the victim, but is not the law itself at fault for having done nothing, or nearly nothing, to protect this young girl? Is it right that one of the two guilty ones alone should support the consequences of a common fault? Such, nevertheless, is the present condition of our law of man, and in the laudable end to protect the family, it has in reality become the protector of seduction. Certainly one cannot consider justifiable homicide as legitimate, and no one has ever tried to do so, at least of late years, although this opinion has been upheld in former times.

In condemning the accused it seems only reasonable to weigh all the various responsibilities and to diminish that which properly belongs to the accused, that which is incumbent upon society as well as that which is incumbent upon the victim. Admitting the necessity of punishing the perpetrators of crimes from passion one should take into consideration the punishment to be inflicted. This should have a double end to attain; firstly, to frighten future criminals, secondly, to repair the morality of the condemned and to give him back to society in the condition of an honest man. Now, if one rightly understands the effect of intimidation of the sentence relative to crimes from passion, its effect on moralization is hardly understood. In point of fact, it is quite certain that the accused is not, under the circumstances, tempted to commit a second crime, like a robber who recommences his exploits as soon as the occasion offers; and, on the other hand, being a perfectly honest citizen, as far as other points of morality are concerned, prison is for him more dangerous than useful. It would consequently seem that a punishment of a particular kind should be inflicted which

should be purely one of intimidation, without any pretention to correct or to moralize. Consequently, the punishment should be similar in its end and execution to a political punishment.

From this it will be seen that we believe in lessening the legal punishment inflicted on criminals from passion, but we would repeat that we do not wish to convey the idea that we consider "justifiable homicide" as either right or excusable. But on account of the admiration that these crimes have given rise to in the romantic school, as well as the excessive severity of modern theorists, who consider crimes from passion as the most dangerous and the most antisocial of all, should not the attention, as well as pity, be drawn to the particular character of these murderers? The present epoch, which is more skeptic, has lost its taste for drama, and Stendhal would say that we have lost energy, when in reality we have merely become possessed of more good sense.

The punishment is not directed against an abstract crime, but a criminal; that is to say, a being having had his past, his honor and his weaknesses; when the crime is an accidental one, its perpetrator should be separated from the army of vice, which populates the prisons. Criminals for a day, they are the victims of one of the most violent passions which afflict human beings. In our eyes they certainly do not merit impunity, but rather a régime appropriate to their past, and especially to their future. In point of fact, at the present time, this class of criminal usually escapes unpunished, but in law they are murderers like any other.

That crimes from passion can never be made to disappear, no matter what measures may be employed, is evident, because an irresistible desire of cruelty slumbers at the bottom of all love. If, since the origin of the theater, if, from Euripides to Racine, from Shakespeare to the Romantics, murder from love has been the subject of the drama, it is because it responds to the sentiments, to the pain and hatred that all may feel and which are quite as imperishable as the human race.

Before proceeding, it might perhaps be well to ask, What is a crime from passion? An eminent magistrate of Paris replied, when asked this question: "There is no crime from passion, and they are merely called such in cases where the jury acquit the criminal. Or, rather, all crimes are from passion, because all are produced by our passions, such as cupidity, or love, ambition or cruelty." That this reply is sound is evident, because when one reflects it will be seen that there is not a single crime committed when all types of passion are lacking.

The expression, "crime from passion" understood and employed currently, is evidently inexact. Crimes from passion are certainly inspired by passion, but they are like all others as far as this is concerned, because some passion is nearly always the cause of a criminal act.

Public opinion, through the voice of the jury, was the first to make notice of and place apart these crimes, and from this very reason, it is readily understood that this term is neither precise nor scientific. The origin of this term is easily understood when one takes into consideration the current acceptation in ordinary conversation of the word "passion." When one speaks of a passion felt by a man, without defining the nature of the passion, it is always attributed to love. Thus understanding the word passion, one would naturally understand that a crime from passion is a crime of love. This, however, is not entirely so, because one should add that in ordinary crimes, passion is in conformity with personal interests, while here it is the contrary; the robber, counterfeiter, or assassin has a passion for money, for gambling or luxury, but when sifted down, the end attained by his crime is to give him some personal profit, a material benefit posterior to the crime committed.

Quite another affair is the cause which animates the criminal from passion. He is essentially disinterested; forced by the violence of his love or of his hatred, after a struggle of more or less duration, he commits his murder, but the crime once accomplished all is finished as far as he is concerned. He has no future benefit to look forward to; the final end that he proposes is the crime itself, and this may be carried to such a point that frequently, his object accomplished, he takes his own life, or gives himself up to justice. Under these circumstances passion plays a much greater part than in ordinary crimes, and becoming in reality an impulse it would seem that it itself committed the crime. From this truth, which at least seems apparent, public opinion had a vague and confused consciousness, in reality quite just, by giving to these crimes the name of crimes from passion. To sum up, and as much as a popular term can be precise, we will consider under the head of crimes from passion those caused by love, which have an entirely disinterested character, and where the violence of the passion alone urged on a normally honest man to commit a crime.

We have just pointed out that a crime from passion was one produced under certain conditions by love. But it may be questioned how love, which is the principle of life and the preservation of the race, can be a cause of death and how a form of affection may result in hatred. To this it may be said that love is an eminently exclusive sentiment and any division is for it a horror. Jealousy is so much the essence of love that the males of wild animals, even of the kindest types, fight among themselves at the time of fecundation. Civilization has not greatly modified these sentiments in man, and Paul Bourget has said: "*Tous les autres appétits, dit un psychologue contemporain, sont plus ou moins contenus dans les barrières sociales; nous nous battons bien pour le pain, comme nos ancêtres des forêts séculaires se battirent pour un morceau de viande crue, mais c'est sous l'œil des gendarmes, et d'après les conditions fixes du Code. L'amour seul est le demeure irréductible comme la mort aux conventions humaines.*"

Vengeance from jealousy is not always a crime; according to the person who is jealous, his social

rank and his nationality, his vengeance will take on such and such a form. It is sometimes calumny, sometimes a subtle address in creating enemies against the loved and hated person. Or to enter into the domain of jurisprudence, it will often be a denunciation, true or calumnious, perjury and so forth, and the list would never end if one were to enumerate all the forms under which hatred and vengeance appear. In 1903 a witness cruelly charged an accused, and when the presiding judge interrupted, saying, "What you are saying is extremely serious for the accused. Have you no motive for wishing to do so?" He received for a reply from the witness: "Your Honor, I was her lover!" — a sentence which had far more import than he realized.

One of the most tragic vengeances which was executed under the form of a denunciation was certainly that of Eyraud, the assassin. Having taken refuge in the United States, he had completely escaped all the investigations of the police and appeared to be forever under cover until his mistress left him. He wrote to the head of the police department in Paris to denounce them both, and in order to bring his mistress to her loss, he himself brought his head to the scaffold.

Occasionally jealousy manifests itself in its violent and primitive loss by murder. A jealous man becomes brutal and agitated; he cannot suffer the presence of any one near the one he loves. From a quiet and good dispositioned person, the becomes easily angered. Never certain of the fidelity of the one he loves, always doubting and always reassured, he makes her unhappy by his reproaches and becomes odious to her by his love. Finally, a day comes when he can no longer contain himself; he gives himself up to his passion and, if he is weak, he seeks justice by an assassination. Whether or not he has resisted the impulse of his jealousy for a short or long time, no argument can be made against him by saying that he might have continued to resist. This would be quite just if the passion was invariable, but such is not the case. Jealousy always increases or may even undergo sudden attacks of violence. After a time this obsession of jealousy produces a dissolving effect on the will of the subject. An honest man may have the temptation to commit some offence; physicians and moralists are fully in accord on this point, but the habit of an honest life in this man has such a power over him, the disproportion between his entire life and this single idea is so great, that there is not even any struggle on his part. As soon as the idea is conceived it vanishes. On the contrary, what makes the temptation to avenge so dangerous in a jealous man is the permanence of his passion.

Jealousy is a continuous pain, or rather one that returns without cessation; it is not a single one, but is multiple; it takes on the most varied forms, coming to the mind for things which are the most foreign to it. It makes the reasoning false by representing murder as an act of justice. It is not merely a mental deviation, it is more especially a moral pain, or even a physical agony.

The idea of vengeance, born from jealousy, thus little by little increases in intensity on account of the persistency of a state that has been quite aptly called by Moreau de Tours a "dislocation of the will." The condition becomes more irresistible from the fact of its duration, just as a body falling to the ground becomes more rapid in its descent the greater the distance is. Thus may be explained the acts of certain individuals who are quiet and good tempered, who on a certain day show an unheard-of ferocity. The death of their victim does not put an end to their anger and they mutilate the cadaver with blows and cuts. We do not think it reasonable to admit that this rage and cruelty changes the nature of the crime, because the fury is merely a proof of the loss of mental control of the murderer much more than the ferocity of his nature.

Upon other occasions the crime is committed after a long period of "chronic jealousy," and then again, on the contrary, a fury ending in a murder arises suddenly. This jealousy and the crime are, under these circumstances, so rapid in development that the murderer is incapable of explaining his act. As examples, I would mention the following instances: A Parisian paper, *L'Evènement*, Dec. 14, 1876, states that a fearful drama took place two days before. Two friends, X and Z, dined together in company with the wife of the former. After the dinner the two men went to play dominoes at a café. After a short time Z said: "I feel tired; I am going to bed early." X let him go without saying anything, but he felt extremely jealous, fearing that his friend had gone to rejoin his wife. He waited a quarter of an hour and then went home, letting himself in rapidly and surprised Z with his wife. Anger got the best of him, and seizing an axe he rushed upon the seducer. "Stop!" cried his wife, throwing herself in front of her lover. In doing this she received the blow from the axe on the shoulder and fell. She was carried to the hospital and died. The accused in this case was acquitted, although premeditation was fully proven at the trial. The well-known murder of Keyes by Gen. Dan Sickles is also similar; Sickles was acquitted on the ground of "justifiable homicide."

Here, on the other hand, is another case which is an example of pure, spontaneous jealousy. A peasant by the name of Dinan was brought to trial for murder. He had been vaguely jealous of his wife, and in a half joking way had said that "any one found in his wife's bed would meet misfortune." On a certain night he went home and found a man with his wife. Insane with anger he threw himself upon him and beat him to such a point that the man died in the night. In this case also the accused was acquitted.

The following case of murder is a still better example of a sudden attack of jealousy. A butcher boy was the lover of his employer, and it had been understood that he should soon marry her. She was a widow and had a son twenty years of age. She asked her lover to wait a year

before the marriage, so that her son could learn a trade in order to support a family. The woman, as may be seen, was most practical and knew how to conciliate the pleasures of love with the duties of maternity, but, before taking another master, she was desirous of profiting by her liberty and found another lover. One day, when she was returning from the country with the latter, she met her fiancé, who at once took in the situation. He immediately asked her to give him an explanation, but she laughingly replied that she was still free and had no accounts of herself to give to any body. Unfortunately a large butcher's knife was there and her fiancé fell upon her, stabbing her several times; then turning his fury upon himself he endeavored to commit suicide by stabbing himself thirteen times. Taken to the hospital in a serious condition he finally recovered. At the trial the accused was found guilty with extenuating circumstances and was condemned to five years' imprisonment.

It should be pointed out that, in this case, the murderer of a mistress by her lover, of a rival by a lover, or the murder of a husband by his wife, are instances which can ordinarily be proven to be accomplished from jealousy alone. These, however, are not the only crimes from jealousy, but when it is a case of murder of the wife by her husband, of a seducer by his victim, there is another sentiment which becomes combined with jealousy, namely, vengeance of an outraged honor, occasionally defence or vengeance for the children, or even a fear of being ridiculed or one of interest.

Beside these crimes, double suicide from passion should also be considered, because, in the first place, jealousy plays the principal part in these cases, and also especially because between the crime and the double suicide there exist a large number of links which unite them and oblige one to examine them together. At the present time suicide is not punished by law but suicide executed by a third party, that is to say, the murder of an individual who consents to be killed, is punished like an ordinary murder, and these instances frequently give rise to trials. In these suicides it ordinarily happens that one of the parties executes the two murders, and usually it is the man who, in the first place, kills his mistress and then himself afterwards. Now, it may happen that when the murder has been accomplished, the sight of the victim troubles the murderer. The mortal blow was well given in the first case, but when it comes to taking his own life, his hand trembles and he cannot give himself the mortal blow. Then again the blood, the cadaver of his victim and the thought of an approaching end calms the mental exaltation, during which he had conceived the project of committing suicide and he hesitates, is seized with fright and does not kill himself. But he is obliged to appear before justice and give an account of his crime.

What is the motive which may force two beings, who love, to their death and who seem to have every possible reason for wishing to live? This motive can be readily understood when some obstacle opposes the union of the two lovers. Frequently this obstacle is to be found in the opposition of parents who refuse to give their consent to the marriage of their son or daughter, on account of the disproportion of fortune or social rank. Young people who cannot thus be united like better to die together than to live separately. They threaten their parents that they will kill themselves, but the former, having passed the age of great passion and romantic ideas, merely shrug their shoulders and only come out of their incredulity after the death of their children.

On the 31st of August, 1897, a young man and a young woman committed suicide in Paris. When dying the young girl wrote as follows to her parents: "Since I have no hope of marrying him I prefer to die with him. Death will unite us forever. I shall be happy. Above all things do not let any one touch my wedding ring."

On the contrary, it may happen that the parents of the young man will not give their consent, as is shown by the following case, which also took place in Paris. In order to prevent the marriage of their son, which they disapproved of, they made calumnious statements relative to the young woman, and when this came to the girl's knowledge she wrote his parents before dying: "To prove to you that I am not a woman belonging to all men, I am going to die with my Léon, because I love him and cannot live without him."

In this last case it would appear quite evident that the suicide had been wished for by the young woman in the first place, but that by jealousy she forced her lover to kill himself. This supposition was confirmed by a letter in which the young man took particular care to defend the memory of his fiancée from this accusation.

(To be continued.)

Clinical Department.

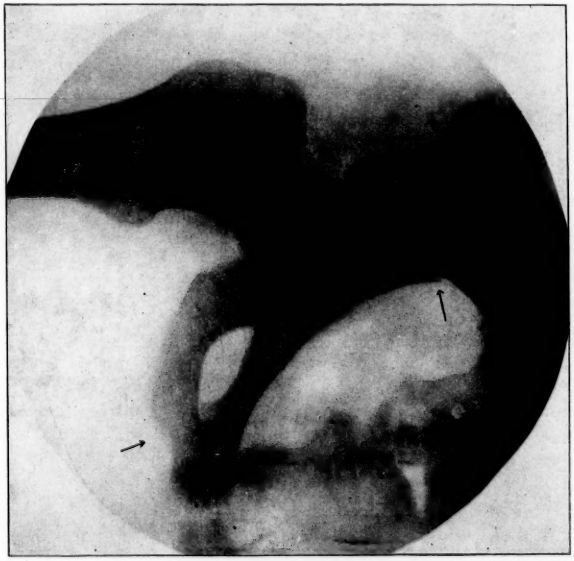
REPORT OF A CASE OF FRACTURE INTO ACETABULUM WITH SEPARATION AT SACRO-ILIAC SYNCHONDROSIS WITHOUT CLINICAL SYMPTOMS.

BY JOHN D. ADAMS, M.D., BOSTON.

THIS case is interesting through the inconsistency of its clinical aspects to the x-ray findings.

A girl, nineteen years old, was struck and knocked down by an automobile going fifteen miles an hour. She was pulled out from under the car and carried into a neighboring store. She was seen ten minutes after presenting the following picture:

Conscious, pulse 120, complaining of pain in left side from hip down to foot.



Examination. — Abrasions on left side with contusion of left hip; motions of left leg somewhat painful; no muscular spasm; no evidence of fracture or dislocation. Walked with limp but with ability to use leg; no limitation of motion in joint; reflexes normal. Acute retention for twenty-four hours. Hyperesthesia over area supplied by lower sacral nerves.

Forty-eight hours later, after rest in bed, was able

to get out of bed and suffered no inconvenience in walking except from general muscular soreness; no limitation of motion at hip-joint; area of hyperesthesia entirely cleared up. Kept in bed.

Five days after the accident the accompanying x-rays were taken by Dr. A. W. George showing a fracture into acetabulum with separation at sacro-iliac synchondrosis.

Plaster jacket applied to pelvis and kept quiet for ten days, at the end of which time jacket removed and examination showed absolutely no disability as evi-

Arrow shows fracture into acetabulum. X-ray taken by Dr. A. W. George.

exist, both incisions are made meeting at the base. The anterior fragment is first made to overlap the posterior, and then the upper portion including the anterior portion is made to overlap the basal portion. This forms a double locking. If the deflection extends into the bony septum the bony deflection is easily broken and replaced with forceps. If the septum is thickened below the horizontal angle the thickened base which protrudes into the formerly obstructed naris should be dealt with as are spurs, etc. If the septum is thin in the lower part and projects unduly into the naris it may be broken into a perpendicular position in line with the upper portion, thus increasing the overlap and making the septum more firm, the bony base soon uniting by bony union. The author passes into the formerly obstructed side a folded piece of antiseptic gauze long enough to extend the length of the former deflection and about one third to half an inch wide, thick enough to pass easily. This should be changed every three or four days until healing is complete, — about four weeks. The instruments used are a

case of a large tumor of the pharynx occurring in a woman of fifty-one years, who at her thirty-sixth year had a grippal attack leaving her hoarse. At the forty-fifth year the breathing became labored, being much worse at night. Two years later she began to choke on particles of food, to have increased dyspnea, difficulty in sleeping, severe headache and vertigo. In her fifty-first year she came under the reporter's observation. A large mass was found to completely fill the laryngo-pharynx, pressing the epiglottis forward

before the marriage, so that her son could learn a trade in order to support a family. The woman, as may be seen, was most practical and knew how to conciliate the pleasures of love with the duties of maternity, but, before taking another master, she was desirous of profiting by her liberty and found another lover. One day, when she was returning from the country with the latter, she met her fiancé, who at once took in the situation. He immediately asked her to give him an ex-

proaching end calms the mental exaltation, during which he had conceived the project of committing suicide and he hesitates, is seized with fright and does not kill himself. But he is obliged to appear before justice and give an account of his crime.

What is the motive which may force two beings, who love, to their death and who seem to have every possible reason for wishing to live? This motive can be readily understood when some obstacle opposes the union of the two lovers. Frequently this obstacle is to be found in the opposition of parents who refuse to give their consent to the marriage of their son or daughter, on account of the disproportion of fortune or social rank. Young people who cannot thus be united like better to die together than to live separately. They threaten their parents that they will kill themselves, but the former, having passed the age of great passion and romantic

Examination. — Abrasions on left side with contusion of left hip; motions of left leg somewhat painful; no muscular spasm; no evidence of fracture or dislocation. Walked with limp but with ability to use leg; no limitation of motion in joint; reflexes normal. Acute retention for twenty-four hours. Hyperesthesia over area supplied by lower sacral nerves.

Forty-eight hours later, after rest in bed, was able

to get out of bed and suffered no inconvenience in walking except from general muscular soreness; no limitation of motion at hip-joint; area of hyperesthesia entirely cleared up. Kept in bed.

Five days after the accident the accompanying x-rays were taken by Dr. A. W. George showing a fracture into acetabulum with separation at sacro-iliac synchondrosis.

Plaster jacket applied to pelvis and kept quiet for ten days, at the end of which time jacket removed and examination showed absolutely no disability as evidenced by limitation of motion, spasm or limp.

Four months after accident examination showed absolutely nothing abnormal.

This case demonstrates very clearly the importance of x-ray in diagnosis as, without doubt, this fracture would have gone unrecognized without x-ray as the case presented no clinical symptoms indicative of its existence.

Reports of Societies.

TRANSACTIONS OF THE TWENTY-NINTH ANNUAL CONGRESS OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

HELD AT WASHINGTON, D. C., MAY 7, 8 AND 9, 1907, IN CONNECTION WITH THE SEVENTH TRIENNIAL CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

(Concluded from No. 12, p. 403.)

THIRD DAY (continued).

STRAIGHTENING THE NASAL SEPTUM.

DR. A. W. WATSON, of Philadelphia, Pa., discussed this question with special reference to the operation devised by him several years ago. It was his view that when a septum could be put in proper place without resection, the patient was better off than if the septal framework had been removed. The methods of his operation for which he claimed originality were the overlap and the beveled, incision. This procedure was applicable to the vast majority of cases. In every case the two conditions to be met and overcome are resiliency and redundancy of tissue. The author thus described his operation: incision on convex side of septum from behind forward just beneath the angle of deflection, following the angle to its anterior extremity and then curving upward for a short distance. This cut should be beveled, and by preference is *not* carried through the mucosa of the concave side. The upper part of the septum is then pushed over the lower portion into the opposite side, thus overlapping the lower portion. If the angle is perpendicular the incision is then made behind the angle, the bevel being from behind forward. An incision is also made at the base forward from the first incision forming a triangular flap. The posterior edge of the anterior portion is then pushed over the posterior portion. If as is frequent, both horizontal and perpendicular angles exist, both incisions are made meeting at the base. The anterior fragment is first made to overlap the posterior, and then the upper portion including the anterior portion is made to overlap the basal portion. This forms a double locking. If the deflection extends into the bony septum the bony deflection is easily broken and replaced with forceps. If the septum is thickened below the horizontal angle the thickened base which protrudes into the formerly obstructed naris should be dealt with as are spurs, etc. If the septum is thin in the lower part and projects unduly into the naris it may be broken into a perpendicular position in line with the upper portion, thus increasing the overlap and making the septum more firm, the bony base soon uniting by bony union. The author passes into the formerly obstructed side a folded piece of antiseptic gauze long enough to extend the length of the former deflection and about one third to half an inch wide, thick enough to pass easily. This should be changed every three or four days until healing is complete, — about four weeks. The instruments used are a straight knife like a tenatome and the same with a blade at an obtuse angle. These suffice for the horizontal incision. For the perpendicular incision a knife with a small blade bent on the flat almost to a right angle and sharp on both edges. The forceps are a modified Adams, the fenestrum being lengthened to an inch and a quarter so as to reach any part of the bony septum.

DR. A. A. BLISS, Philadelphia, had had much satisfaction with the Watson operation. Sub-mucous resection was being overdone. For the angular deflections the Watson operation was preferable.

DR. EMIL MAYER would also commend the Watson operation for angular deflections. He would like to lay stress on the matter of freshening the edges of the floor on the concave side after having performed the operation on the convex side. This gives a double opportunity for holding the part pushed over into the concavity. He preferred hard rubber tubes to gauze for packing. No one operation sufficed for every case.

DR. W. E. CASSELBERRY asked if it was not possible to obviate the second operation sometimes called for, namely, the removal, as we would take off a spur, of the thickening along the long part of the horizontal cut protruding into the naris of the convex side after healing. The Watson operation could be done quickly, efficiently and without difficulty. He preferred to operate under general anesthesia.

DR. WATSON stated that by preference he went through the mucosa of one side only but this restriction was not always possible.

DR. L. BALLENGER, Chicago, thought that if we could save the framework of the septum it was most advisable to do so. He had one sinking in of the nose after a sub-mucous operation, not having made due allowance for the chondritis undoubtedly following the injury.

DR. R. C. MYLES referred to the various operations devised during the last few years. Submucous operations were not free from danger, as he knew of two cases resulting fatally. The deeper the operation on the bony septum, the greater the element of danger. He thought the perpendicular plate of the ethmoid a very difficult thing to handle.

DR. J. SOLIS-COHEN made comparisons between the mechanical principles involved in the Watson and in the Gleason operations. He had seen serious cerebral effects follow the latter.

Discussion was closed by DR. WATSON.

LARGE TUMOR OF THE LARYNGO-PHARYNX REMOVED BY SUBHYOID PHARYNGOTOMY.

DR. W. F. CHAPPELL, of New York City, reported the case of a large tumor of the pharynx occurring in a woman of fifty-one years, who at her thirty-sixth year had a grippal attack leaving her hoarse. At the forty-fifth year the breathing became labored, being much worse at night. Two years later she began to choke on particles of food, to have increased dyspnea, difficulty in sleeping, severe headache and vertigo. In her fifty-first year she came under the reporter's observation. A large mass was found to completely fill the laryngo-pharynx, pressing the epiglottis forward

against the root of the tongue and laterally touching the pharyngeal wall. Posteriorly it extended downward some distance and it was difficult to see how the patient could breathe or nourish herself. The laryngeal interior could not be seen. The surface of the mass was covered with large tortuous vessels. A low tracheotomy was done under cocaine. Later an effort was made to remove the growth with a cold wire snare but adhesions prevented. The solid nature of the tumor was determined by introduction of a curved scalpel. A subhyoid pharyngotomy was then done. The pedicle was found close to the left ary-epiglottic fold and was tied off with a silk ligature. The circumference of the mass was four and one-half inches, and it was found to consist of fibrous tissue very moderately supplied with nuclei and round cells. The patient made a good recovery. Difficulty in nutrition caused some scorbutic symptoms but these were promptly relieved by fruit acids. The reporter had found records of eleven similar growths.

PLEA FOR LOCAL ANESTHESIA IN OPERATIONS ON THE MAXILLARY SINUS.

A paper with this title was read by DR. GORDON KING, of New Orleans. He took the position that we ought to minimize the dangers of anesthetics as much as possible and that we ought consequently to employ local instead of general anesthesia whenever and wherever possible. In operations around the mouth and pharynx, general anesthesia caused annoyance and delay from nausea and vomiting, inhalation of blood secretions into the larynx and frequent interference with the administration of the anesthetic. The author was led to employ local anesthesia in antrum operations two years and had used them only since that time. He is a loyal adherent of the Caldwell-Luc operation and has been able to finish it in less than twenty minutes. He swabs the mucosa briskly with a 10% cocaine solution, and when the area has become insensible to the needle point, he injects a solution of 2% strength with 1-2000 adrenalin along the line of incision, at first superficially into the submucous tissue and later into or under the periosteum. This done, incision is made down to the bone and the periosteum elevated until the exact situation of the infra-orbital foramen can be made out when, to insure perfect and widespread anesthesia, a few drops of the solution are injected into or around the trunk of the infra-orbital nerve at its point of exit. He finds it prudent not to lay bare the nerve itself as this may lead to post-operative neuralgia or neuritis. The bone being sufficiently exposed to allow of easy access to the antral cavity, the latter is opened with a chisel or electric burr when several drops of 10% cocaine and some adrenalin are introduced into the cavity which is then swabbed by means of a cotton carrier. A few minutes must be allowed at this point for absorption of the solution, and the time may be utilized by applying a pledget of cotton saturated with the solution under the inferior turbinate where the counter-opening is to be made into the nose. The antrum is then curetted, the counter-opening made and the buccal wound sutured. Adrenalin lessens the blood flow and prolongs the effect of the cocaine while offsetting the toxic tendency of the latter. The author has followed the foregoing plan in some 15 cases and with most satisfactory results. In two instances he has performed the radical operation on the frontal sinus under local anesthesia, but here the results have not been so satisfactory, as this region is more sensitive and less susceptible to thorough cocainization.

DR. R. C. MYLES stated that he had operated on 200 antral cases during the last fifteen or twenty years, but that during the last eight or ten years not more than 2% of the operations were done under general anesthesia. He had gradually diminished the strength of the cocaine solution until now he rarely used more than ¼%. The operation was practically painless unless we got near some dental nerve. Water, by its pressure on the nerves, sometimes gave as good anesthesia as did cocaine. Of late years he had preferred the nasal route, introducing a light platinum needle under the inferior turbinate and then introducing the cocaine and adrenalin through the opening thus made, for the most of the pain was in the antral mucosa. He did not believe in putting the cocaine on a region on which he did not intend to operate and therefore considered it unwise to spray it indefinitely. He knew of several deaths from general anesthesia. They were more than published reports would lead us to believe.

DR. W. E. CASSELBERRY could also commend the use of local anesthesia for these operations. He had not been able, however, to operate as quickly as had Dr. King. The injection of some of the solution into the region of the infra-orbital nerve, as had been suggested by Dr. King would doubtless be a very useful addition to the procedure.

In closing the discussion Dr. King said that local anesthesia facilitated the operation. It avoided all the objections which arise from the use of a general anesthetic in operations about the mouth. After an opening was made into the antrum, a 10% solution could be injected and by the time the antrum was thoroughly opened it was insensitive to pain. A still stronger solution could be swabbed on the interior surface of the cavity.

MYXO-FIBROMA OF THE NASO-PHARYNX.

After some general observations on tumors of this nature occurring in the naso-pharynx, DR. D. BRADEN KYLE presented a specimen removed from a man of twenty-four years who complained of inability to breathe and of almost continuous pain or aching in the region of the frontal sinus or over the bridge of the nose. On the right side a mass almost protruded from the naris. The mirror outlined a mass in the naso-pharynx but it did not extend below the margin of the soft palate. There was considerable catarrhal discharge but no evidences of sinus or ear trouble. A distinct swelling was evident at the inner corner of the right eye. The left naris was occluded owing to pressure of the tumor on the septum. The mass was removed without difficulty, and six weeks later the patient was in good condition with both nares of practically the same size. The interesting points in the case were the site of origin, at the posterior end of and under the superior turbinate, the symptoms of nasal occlusion by septal pressure, the fact that the growth did not follow the path of least resistance, the practical absence of hemorrhage, the pedunculated nature of the mass removed, the absence of ear and sinus involvement. The bony septum seemed to have been softened by the pressure and inflammatory process. It was easily forced back into the median line by the nasal dilator and remained in position without the aid of splints.

DR. JOHN W. FARLOW stated that one symptom in a patient of his and not present in that of Dr. Kyle was a change in the voice. The growth was larger even than in Dr. Kyle's case. The character of the voice changed immediately after the tumor was removed. His patient had formerly pronounced the letter *m* as *b* but as soon as the growth was removed the *m* came out very clearly.

DR. A. W. WATSON had had a similar case in which the circumference of the growth was about six inches. It had involved both sides of the septum and extended

into one antrum producing some facial protrusion on that side. The large mass filling the naso-pharynx was removed with the snare. The entire vault of the pharynx was covered, however, with similar material and was reproduced as fast as it was cleared away, but under the influence of electric needles it began to diminish and finally ceased growing.

Dr. Gordon King had recently removed a myxo-fibroma as large as a hen's egg and found the site of attachment to be the ala of the nose.

Dr. William Lincoln, Cleveland, said that not all cases were so favorable as was that of Dr. Kyle in regard to distribution of blood vessels. In a recent case of his own, snares and forceps were useless and he was obliged to remove the nose on one side, lay it over on the face and so gain free access to the tumor. Adhesions were separated with the spatula and the cautery used. In removing the nose he had cut in on the sound side so that the inevitable suppuration was discharged not through the wound but into the pharynx. The mass projected into the naso-pharynx and needles were used here, as explained by Dr. Watson.

Dr. J. N. Mackenzie gave the history of a case illustrating the occasional impossibility of removing these tumors through the internal passages. They might become rooted in many places. In one instance he had been compelled to turn the patient over to the general surgeon who did a modified Langenbeck operation dissecting out the growth in that way. Severe hemorrhage accompanied the procedure.

Dr. W. E. Casselberry said that the tumor mentioned by the last speaker was probably a fibroma, while Dr. Kyle had spoken of myxo-fibroma which was quite another form of neoplasm. The two conditions should not be confused because the treatment of one was entirely different from that of the other.

Dr. Kyle, in closing the discussion, said that it was difficult to see why such soft growths should cause so much bony displacement.

Epithelioma of the Tongue; Early Diagnosis; Operation; Recovery.

The history of the case was presented by Dr. Robert C. Myles, of New York, whose patient was a man of sixty-four years, who had been annoyed for a few weeks before coming under observation by a sensitive spot on the left side of the tongue, a little in front of the insertion of the palato-glossus muscle. At this site there was a small, hard and roughened area suggesting malignancy. Iodides were tried without avail and operation was decided on. This was done by Dr. J. A. Bodine who thoroughly dissected out all the superficial and deep cervical glands and also the submaxillary, salivary and sublingual glands and much of the connective tissue along the jugular vein and carotid artery in order that many of the small undetectable lymphatics might be removed. Then, with heavy scissors, section was made of the affected area in healthy tissue at a distance of from one half to three quarters of an inch from the margin of the growth. It was necessary to sever the left palato-glossus muscle and parts of the genio-hyo-glossus, stylo-glossus, hyo-glossus and lingualis. This caused the tongue to curl upward at the tip and to fall back on the epiglottis at the left base. The patient made a good recovery from the operation which was done six months ago. The microscopist reported that the growth removed was a squamous-celled carcinoma. The glands removed were somewhat inflamed but showed no metastases.

Dr. J. H. Bryan, Washington, was very much interested in the subject of cancer of the tongue, and related the histories of two personal cases under his recent care. The fate of the patient depended on the early recognition of the disease. The cases should be recognized in the pre-cancerous stage. Recurrence sometimes occurred on the side opposite to that of the original disease because of the richness of the tongue in lymphatics, the circulation of which the raphe was not able to shut off. The glands ought to be excised on both sides.

Dr. J. N. Mackenzie said that the Baltimore surgeons believed that the whole floor of the mouth ought to be excised.

Dr. George E. Shambaugh, Chicago, said that he had had a recent case of cancer of the neck which seemed to him to be rather unusual. He thought that the development of the tongue explained it. The anterior part of the tongue developed in halves while the back part developed as a central piece.

Dr. Myles closed the discussion.

At the closing executive session it was announced that the retiring President, Dr. de Roaldes, had offered the Association five hundred dollars for the establishment of a prize fund. This offer was gratefully accepted and it was voted to attach to the fund the name of the donor.

The following gentlemen were elected to membership: For Honorary Fellow, Prof. Leopold Von Schroetter, of Vienna (transferred from the list of Corresponding Fellows). Active Fellows: Dr. Joseph S. Gibb, Philadelphia, Pa., proposed by Drs. Lincoln and Packard. Thesis, "Is there an Ideal Operation for the Correction of Deviations of the Nasal Septum?" Dr. Christian R. Holmes, Cincinnati, Ohio, proposed by Drs. Kyle and Mayer. Thesis, "Pyogenic Diseases of the Accessory Sinuses of the Nose and the Etiology of Facial Erysipelas, Including Secondary Effects upon the Eyes." Dr. Chevalier Jackson, Pittsburg, Pa., proposed by Drs. Freer and Harris. Thesis, "Ligation of the External Carotid Artery from the Pharyngo-rhinologic View Point; Report of Cases." Dr. George E. Shambaugh, Chicago, Ill., proposed by Drs. Rhodes and Casselberry. Thesis, "The Architecture of the Ethmoid Labyrinth." The election of officers for the coming year resulted as follows: President, Dr. Herbert S. Birkett, Montreal; First Vice-President, Dr. J. Payson Clark, Boston, Mass.; Second Vice-President, Dr. J. Edwin Rhodes, Chicago, Ill.; Secretary and Treasurer, Dr. James E. Newcomb, 118 West 69th Street, New York City; Librarian, Dr. Joseph H. Bryan, Washington, D. C.; Member of Council to serve for four years, Dr. A. W. de Roaldes, New Orleans, La. The determination of date and place for the next Congress will be decided by the Council. The meeting was the largest in the history of the Association.

Book Reviews.

Surgical Instruments in Greek and Roman Times. By John Stewart Milne, M.A., M.D., Aberdeen; Keith Gold Medalist in Clinical Surgery. With illustrations. Oxford: at the Clarendon Press. 1907.

This is a gem of a book, in refreshing contrast to many of the commercial productions with which the publishers are flooding the medical-book market. It is original, sincere and thorough. The author, a young man and a recent graduate in medicine, has devoted six years to

the collection of his material and gives us this monograph as the thesis which formed part of the examination for the degree of M.D. of the University of Aberdeen. It was successful in gaining "Highest Honors." One must believe the writer to be an accomplished linguist, with a familiarity with languages ancient and modern far greater than we see in the average medical graduate. He has read searchingly, and in the original, the works of Hippocrates, Celsus, Aretæus, Galen, Oribasius, Soranus, Aëtius, Paul of Egina and dozens of others, — Greek, Latin, Arabic and medieval writers, while he acknowledges modestly his deep obligation to the distinguished English scholar, Francis Adams. The writing is so thorough and convincing that one feels we have among us again an English-speaking medical historian of the first rank. And Milne is evidently not only an historian but an accomplished physician.

The author divides his book into eleven chapters and two appendices, with a satisfactory index — English, Latin and Greek. He recalls for us, first, the famous surgeons of antiquity, glancing hastily at some of their contributions to our art and describing the instruments which they enumerate. It is an interesting fact that recent excavations and discoveries have now put into our hands material for such a book as this, for Milne explains that Adams, writing sixty years ago, was unable to account satisfactorily for many of the instruments he describes, because sixty years ago the actual instruments had not been discovered to illustrate and make definite such writing. Truly, as the author states, comparatively little attention has been given to this department of archeology. Whatever literature we have is entirely continental and consists of a series of reports of different finds, with attempts to indicate the uses of the instruments described.

Every chapter of Milne's book bristles with novel and refreshing information. One learns with keen interest how both the Greeks and Romans made their instruments of finely tempered steel as well as of the more common bronze. Unfortunately, while the bronze has survived, most of the steel has been oxidized and has disappeared. The ancients used ores of a high quality, and we are told of the heaps of scoriæ left in the Forest of Dean by the Roman founders, — refuse which contains so large a percentage of iron still remaining that the scoriæ were melted over again in later times and occupied more than twenty furnaces for two hundred years.

The ancients used bronze — a mixture of copper and tin — for many instruments, especially for instrument handles, for ornamentation and for instrument and medicine cases; and they employed other metals as well as horn, wood and stone for appropriate utensils.

The most prolific sources of finds are the excavations at Herculaneum and Pompeii, but there are numerous others of less richness throughout Italy, France, Greece, and even Germany, for we learn that so lately as 1893 important excavations in the Roman military hospital at Baden resulted in an extensive find.

Space does not allow a detailed description of the ancient instruments, but one notes especially the character of the operating knives with blades of steel and handles of bronze, the nearer end of the handle ornamented with a leaf-shaped spatula to act as a blunt dissector much like the useful knife which J. Collins Warren recently has popularized. Knives were of all shapes and varieties from the long amputating blade to the delicate instrument used for plastics of the eyelid. There were shears and scissors also; and there were probes and specula, especially of the tri-valve type as Milne shows in his interesting illustrations. (Recently this reviewer saw a model of a Pompeiian trivalve speculum in the possession of Roswell Park.) The specula, probes and knives with their uses are graphically described by the author, though the modern surgeon shrinks at a rehearsal of elaborate operations performed without anesthesia or asepsis upon such organs as the brain and intestines. Few books bring before us so clearly the details and terrors of that ancient surgery. We read also of the needles and bodkins of Hippocrates, of uterine sounds and dilators, of blunt dissectors and curved hooks, and of forceps of great variety. One is interested to learn that the common form *Vulsellum* finds no authority in classical usage, for the Romans wrote *Vulsella*, — æ feminine. Bleeding cups and clysters have less interest for modern readers, though the custom of cupping is mentioned in the Hindoo Vedas; but we read of the syringe, commonly constructed of a leather bag, armed with a metallic tube, a form which held its own until the early part of the nineteenth century. Cauteries were in common use and were made of iron, *ferrum candens* being the familiar term. There were elaborate bone and tooth instruments, rongeurs, chisels, gouges, drills, saws, trephines, heavy bone-forceps, files, scoups and numerous other instruments, coarse and fine. Milne devotes an interesting chapter to the gynecological instruments of the ancients. There is no evidence that they used obstetric forceps, but they had instruments for destructive operations upon the child, and they employed uterine sounds, curettes and pessaries. Hippocrates and Antyllus describe methods of disinfecting with steam the uterus and vagina in septic cases. The ancients used sea sponges fresh, with the smell of the sea upon them, and dipped in wine. Galen tells how he has checked hemorrhage by applying a sponge dipped in asphalt to a bleeding wound and setting fire to it, leaving the unburned part to cover the wound. The Greeks and Romans employed sutures commonly, made usually of flax or wool, sometimes of human hair. They used also metal clasps and bands to unite broken bones and severed soft parts.

Such are the subjects with which the author deals, and he tells his story pleasantly and lucidly, illuminating his text with many pictures. Our JOURNAL readers should turn aside and devote an evening to this delightful book.

Manual of Anatomy, Systematic and Practical, Including Embryology. By A. M. Buchanan, M.A., M.D., C.M., F.F.P.S. Glas., Professor of Anatomy in Anderson's College, Glasgow, Examiner in anatomy for the triple qualification of the Scottish licensing bodies, etc. Vol. II. Pp. 1539. Illustrated. Chicago: W. T. Keener & Co. 1907.

In our issue of Dec. 6, 1906, we reviewed the first volume of this work on anatomy. The second volume has now appeared, including a discussion of the abdomen, thorax, head and neck, nervous system, organs of special sense, together with an appendix containing the Basle nomenclature and a glossary. Naturally the method of presentation adopted in the first volume has been continued in this, the most notable feature of this arrangement being that the development of organs and structures is considered with the general descriptive anatomy. The book is amply illustrated, as was its predecessor, and colors are freely used. The paper is good and the type clear. We again call attention to the flexible buckram covers, which, if soiled during use, may be cleaned with a moist sponge. From a practical and esthetic standpoint this should appeal especially to the student who continuously uses the book in the course of dissection. In general the book will take its place among others of high rank in the science of which it treats.

Foods and Their Adulteration. Origin, Manufacture, and Composition of Food Products; Description of Common Adulterations, Food Standards and National Food Laws and Regulations. By Harvey W. Wiley, M.D., Ph.D. With eleven colored plates and 86 other illustrations. Pp. 625. Philadelphia: P. Blakiston's Son & Co. 1907.

In this work, the author, who is chief of the Bureau of Chemistry, of the United States Department of Agriculture, and who has been humorously described in the secular press as the "janitor of the people's insides," has brought together a mass of interesting information concerning the many articles of food of mankind, and has illuminated it with sidelights from his own very interesting personality. Although in his introduction he says: "The American public is now so well educated that any average citizen is fully capable of understanding scientific problems if presented to him in a non-technical garb," he appears to deem it necessary to inform his readers that "soups are generally used at the beginning of a meal, usually at dinner time"; that "lard has come to be looked upon as a necessity in every kitchen, even of the humblest citizen"; that "both hens and roosters are used for food purposes, but especially the young roosters are devoted to food purposes, while the young hens are often [yes, very often] kept for the production of eggs"; that "for food purposes the chicken is eaten at various ages"; that "the principal domesticated fowls which are used for human food are chickens, turkeys, ducks and guinea hens," and that "lard is sometimes [!] employed for the purpose of cooking by the process of frying"; furthermore, to this well educated public he takes pains to make clear the difference between veal and beef, lamb and mutton, pig and pork, and to explain that the "eggs which are principally used for food" are those of the domesticated fowl, chiefly "chickens, ducks and geese." When told that "fish are known chiefly by their common names," the irreverent might truly ask by what other name than those could they be chiefly known. We doubt that but for this work it would have been known that "the size of the fish usually depends upon the magnitude of the body of water in which the species grow," and cannot but feel grateful for the citation of at least one exception — "The size of the whitefish in the Great Lakes is not so great as the extent of water would indicate." One may be moved to inquire why whitebait, smelts and flounders, which are indigenous to the Atlantic, are so much smaller than whitefish from Lake Superior, which in its magnitude is so vastly inferior to the ocean. But now we know, at least, why brook trout do not approach in size the sturgeon and horse mackerel and why shiners are unequal to halibut,— the magnitude of the bodies of water in which they grow is inadequate.

The author's principal obsessions appear to be the use of artificial colors and misbranding. All colors, however innocent their nature, and notwithstanding the sanction of long usage, should be barred. The coloring of winter butter is "reprehensible"; the coloring of factory cheese is "reprehensible"; all coloring is fraudulent and "reprehensible." Misbranding is even worse. What can be more wicked than calling herring, boxed on the coast of Maine and sold at a few cents per box, "sardines"? What punishment can fit the crime of making a cheese in Ohio and labelling it so as to convey the impression that it was produced in New York? These are far from harmless frauds. Lima beans should come exclusively from Peru and Brussels sprouts from Belgium!

In the kitchen our author is especially refulgent. Clam soup is made of clams, milk, cream, flour, and condiments; put in more clams and some potatoes and we have clam chowder.! That sort of chowder may pass in Kent County, Ind., but not in the habitat of the clam.

Throughout the work appears constantly a plea for Federal inspection — "municipal, state and Federal inspection" — by experts, and especially Federal experts, of which the author is the acknowledged chief.

The book is copiously illustrated — 11 colored plates and 86 figures, taken mostly from Farmer's Bulletins and other documents distributed during the past fifteen or more years by the Department of Agriculture. Of the 11 colored plates, 7 are "reproduced by courtesy of Armour & Co., Chicago." Apart from the impropriety of the director of the Federal inspection force placing himself under any obligation whatever to a con-

cern whose methods were for a time a stench in the public nostrils and whose canned products as sold in Massachusetts were shown by the State authorities, a year ago, to need that "municipal, state and Federal" inspection which the author advocates so warmly, it is to be wondered why these plates were introduced, for although the author says, "By comparing the appearance of the beef bought in all markets with these plates it is possible to form a sound judgment of their suitability for consumption," they teach nothing whatever of the sort and serve no purpose other than padding; and this may be said also of a large proportion of the illustrations in general, including the 7 out of nearly 100 contributed by the author and not borrowed from other works.

Although credit has been freely given for the illustrations, it is otherwise regarding tables and facts, and the author appears to be guilty, too, of more or less "faking," an example of which is giving Storch's figures for a buttermilk standard, although without credit, and filling in the space for acidity, which Storch fills with an interrogation mark, with a figure from a similar table by Vieth. On the whole, in spite of its blemishes, the book will serve to some extent a useful purpose.

The Eye and the Nervous System: their Diagnostic Relations. By various authors, edited by WM. CAMPBELL POSEY, A.B., M.D., and WILLIAM G. SPILLER, M.D. 8vo, pp. xii, 988. With 239 illustrations and 13 plates, 8 of which are colored. Philadelphia and London: J. B. Lippincott Co. 1906.

Oppenheim's dictum, that he who cannot use the ophthalmoscope is no neurologist, although not yet fully recognized, is only a part of the truth. The neurologist needs a far wider knowledge of the eye and its functions than can be obtained solely by the ophthalmoscope, but, unfortunately, such knowledge is only too often lacking and our medical curricula fail to insist upon it as a preliminary to the study of neurology. It is equally true that the ophthalmologist should have an accurate knowledge of the functions and diseases of the nervous system. Any work, therefore, which tends to bring together these two branches of medicine is welcome. In the plan of such a work two principles may be adopted: the plan may be based upon the eye itself, studying its functions and noting the significance of their alteration in diseases of the nervous system, or it may be based upon the nervous system, studying the individual diseases and noting the eye symptoms occurring in them. The former plan is certainly to be preferred. Optic neuritis, abducens paralysis, or an Argyll-Robertson pupil is a natural starting point for inquiry, whereas paralysis agitans, cerebral hemorrhage or trigeminal neuralgia rarely is attended with ocular symptoms worthy of note. The editors of the present work, however, have adopted neither of these nor any definite plan, but have divided the book into various chapters which do not form part of one consistent whole but seem rather designed to hold an even balance between the neurological and ophthalmological contributors. The result is that, like most of the composite works that are forced on us by zealous publishers, the book is without plan, and contains much that is irrelevant. Some contributors give a good account of certain nervous disorders, with perhaps an incidental mention of the ocular symptoms; others limit themselves closely to an exhaustive consideration of the ocular symptoms, and the ocular symptoms only, that occur in the diseases treated. The book contains no diagram showing the relations of the optic fibers in connection with hemianopsia, yet it contains elaborate chapters on the wholly irrelevant questions of nerve anastomosis in facial paralysis, the Gasserian ganglion operation for tic douloureux, tremors, reflexes and gaits. The great question of the etiological importance of eye-strain is left almost wholly to ophthalmologists, who take a somewhat extreme view of the subject, although they do not endorse wholly the teachings of Ranney and Gould. It is a great pity that the question was not more fully discussed from the neurological standpoint. Nevertheless the book, despite its lack of plan and its poor arrangement, despite too the uneven merit of all composite works, contains some chapters of extreme value, some that are merely commonplace, but on the whole very much that both the neurologist and ophthalmologist will find indispensable, although the inevitable comparison with the great work of Wilbrand and Saenger is decidedly against the volume before us. The index is very unsatisfactory.

Space is lacking to consider each contribution separately, but we will add the list of contributors, with their respective subjects. W. G. Spiller writes on the anatomy of the cranial nerves; W. N. Souter on the structure and optical properties of the eye; C. K. Mills on the psychology of the visual act and the focal diseases of the visual cortex; C. A. Wood on the external examination of the eye; Alexander Duane on the extra-ocular muscles; J. E. Weeks on the intra-ocular muscles; Edward Jackson on affections of the fifth, seventh and cervical sympathetic nerves; H. V. Würdemann on diseases of the retina and optic nerve; W. G. Spiller on tumors of the brain; E. W. Taylor on bulbar and pseudo-bulbar diseases; Wm. Hirsch on arteriosclerosis, multiple sclerosis, Friedreich's disease and paralysis agitans; F. X. Dercum on parasyphilitic diseases, insanities and toxic encephalopathics; B. Sachs on amaurotic idiocy and cerebral infantile paralysis; C. W. Burr on acromegaly, abnormalities and hemiatrophy; T. H. Weisenburg on diseases of the spinal cord and nerves; G. E. DeSchweinitz on hysteria and other neuroses; J. H. Lloyd on ingrains, epilepsy and tetanus; S. D. Risley and H. F. Hansell on eye-strain; W. C. Posey on exophthalmic goitre and the psychological effects of operations on the eye; C. H. Frazier on the surgical treatment of intracranial lesions causing disturbances of vision; Joseph Sailer on tremors, reflexes and gaits; and G. L. Walton on degeneracy.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 26, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 Boylston Street, Boston, Mass.

DEATH OF DR. JAMES CARROLL.

The death of Dr. James Carroll should not be allowed to pass with merely a perfunctory notice of his career. He belonged to that small class of men who are willing to undertake a most serious personal risk in order to demonstrate the truth or falsity of a theory. To permit himself calmly and with full knowledge of possible consequences to be bitten by a fever-infected mosquito was a simple act of heroism which we shall do well to honor. Although Dr. Carroll, after undergoing a severe attack of yellow fever, recovered from the disease, it left its traces behind in the form of an affection of the heart which undoubtedly ultimately resulted in his death, which occurred on Sept. 16, in Washington.

Dr. Carroll, at the time of his death major and surgeon in the United States army, was born in Woolwich, England, June 5, 1854. He enlisted in the United States army in 1874, serving as private, corporal and sergeant in two infantry regiments. From 1883 to 1898 he served as hospital steward, employing his time during the latter part of this service in the study of medicine. He was finally graduated in 1891 from the Medical Department of the University of Maryland, and thereafter prosecuted his studies further in the Johns Hopkins Hospital. He early showed a special interest in laboratory investigations, and, therefore, it was not a surprise that he was chosen in 1897, together with Dr. Walter Reed, Dr. James W. Lazear and Dr. A. Agramonte, to serve as a member of a commission to investigate yellow fever in the United States. Experiments made at that time quickly demonstrated the probability of the spread of the disease by mosquitoes, and a human subject seemed essential for the demonstration of the correctness of this supposition. Dr. Carroll was the first to offer himself for the purposes of this vitally important experiment, with the results which are now generally known and which have been emphasized by the circumstances of his death. In somewhat broken health Dr. Carroll maintained his interest in matters of bacteriology and pathology, and in 1899 received a commission in the medical department of the army. In 1907, although too enfeebled in health to take an active part in further investigation, he received the commission of major and surgeon, retaining his position as curator of the Army Medical Museum. Dr. Carroll held a wide society membership, and was an instructor in bacteriology and allied sciences in the Army Medical School as well as professor of bacteriology and pathology in the George Washington University.

Dr. Carroll was an earnest student and an enthusiastic investigator on the subject of infection, but his chief claim to perpetuity will undoubtedly lie in the spirit of self-sacrifice which led him to accept a very real danger in the hope that by his example and in a measure through his instrumentality a unique and far-reaching doctrine might be substantiated. Many others followed Dr. Carroll in offering themselves as subjects for experimentation, fortunately with no deaths, but this does not in the least detract from the honor due Dr. Carroll in being the first to receive the inoculation. It is a somewhat pathetic fact, and possibly a commentary on the hard and self-sacrificing work of our scientific investigators, that but one of this now famous commission appointed to investigate yellow fever is living. None of these men had reached the acme of his usefulness, but the accomplishment of each was quite sufficient to give him a high place among the real benefactors of the human race.

IMPROVED HEALTH OF SCHOOL AND COLLEGE STUDENTS.

In the many articles appearing nowadays on the diseases incident to school life and the generally injurious effect of grade and high school conditions, the brighter side seems to have been quite overlooked. This is, that the scholars who graduate from our high schools to-day are taller, heavier and stronger for the same age than they were a generation ago. This statement holds both for the boys and girls.

In 1899 Dr. Paul C. Phillips, now in charge of

the Department of Hygiene and Physical Education at Amherst College, prepared some statistics for a periodical which was attempting to answer the question, Shall we become a race of giants? These figures were amplified and published in the *Physical Education Review*, June, 1904, under the title, "Is the Physique of the American College Man and Woman Degenerating?" They showed beyond a peradventure that the boy who goes to college to-day is taller and heavier and the girl taller, heavier and of greater chest girth than the boy and girl of the same age from forty to fifty years ago.

Mr. J. H. Vines had in 1899 found the same facts to be true in England, the boys in Marlborough and Rugby schools, ranging from twelve to eighteen years of age, being both taller and heavier at the same age than their fathers had been a quarter of a century before.

Of the girls examined at Smith College in 1900–03, those at seventeen years showed a superiority of a half inch in height, three pounds in weight and two thirds of an inch in chest girth over those at the same age 1883–88. At eighteen years the superiority amounted to three-fifths inch in height, nearly three pounds in weight and a half inch in height. These were, in general, corroborated by figures from Wellesley, Oberlin, Chicago and Mt. Holyoke colleges.

The Amherst College figures are from thousands of students and very reliable. They show the average heights and weights of students seventeen to twenty years of age to be as follows in three different periods:

HEIGHT OF AMHERST COLLEGE STUDENTS.

Age.	1860–84.	1884–94.	1900–03.
17 years	66.8 in.	68.0 in.	68.2 in.
18 "	67.0 "	68.1 "	68.4 "
19 "	67.1 "	68.2 "	67.7 "
20 "	67.5 "	68.3 "	68.3 "

WEIGHT OF AMHERST COLLEGE STUDENTS.

17 years	128.7 lb.	130.8 lb.	129.9 lb.
18 "	131.1 "	133.6 "	134.5 "
19 "	133.1 "	136.4 "	135.6 "
20 "	135.0 "	138.0 "	138.2 "

The statistics for 1900–03 would probably show the superiority more clearly were they as numerous as those for the preceding periods. The measurements of freshmen for the years since 1903 show the class averages even higher in height, weight and strength than they were in the years 1900–03, although the average age is somewhat less.

It is not claimed from these statistics that we will be a race of giants in 1950; thousands of years have changed stature but little, as Prof. Carl Pearson has shown; neither is it assumed that because height and weight increase, morbidity decreases. Educators and militarists are of the opinion, however, that an increase in the height and weight of the race would be desirable as indicating more complete growth and development. These two factors in racial improvement physically are certainly increasing.

There is evidence to show also that health, in our colleges at least, is improving. The president of one of our New England colleges, a man of unquestioned good judgment, in his report to the trustees in 1854 stated, "The waning of the physical energies in the midway of the college course is almost the rule rather than the exception among us, and cases of complete breaking down are painfully numerous." Such statements sound strange in our ears to-day. The health of students is generally better at graduation than on entering college, and the same might probably be said of our high schools, except in so far as health is modified by the pubertal period. While, therefore, much still remains to be accomplished in the field of school hygiene, we may encourage ourselves by the thought that we are physically not worse than our fathers and mothers.

COCAINE AND THE NEGRO.

POLITICAL history has perhaps never presented a graver problem than that which centers in the American negro. Centuries ago some among this unhappy people were taken from their native soil, brought hither and compelled to slavery. Recognizing that it is the white race which has primarily been responsible, the most humane among our fellow-citizens in the South, and its profoundest statesmen, are giving earnest and anxious thought to this problem; yet there is not one of them who is able to give a satisfactory solution of it.

This much is, however, becoming recognized: that to-day this question is taking on a phase which has not heretofore characterized it. The "before-the-war" negro was a genial and harmless creature. His loyalty was proverbial; the Southerner at the front did not hesitate to intrust wife, family and home to his care, and this at a time when he could easily have indulged evil propensities had any such existed. His greatest fault was alcoholism. But a drunken negro, though he might be noisy and a little contentious, was easily managed; he was even then

neither vindictive nor savage in his tendencies. Although the malign influences of the carpet-bagger and of the reconstruction period should have tended much to alter the character of the negro, it has, nevertheless, up to recent years remained decent, amiable and law-abiding.

But now an entirely new phase of the situation is manifest to those who are willing to accept facts. Many negroes are now guilty of most insensate crimes, such as are inexplicable upon any natural basis. Nor are these crimes committed in unsophisticated rural districts, no matter how dense may be the negro population in them; they are done especially in cities, or near mining, lumber, railroad and like camps, where industrial operations on a large scale are in progress. Nor are these crimes, as is so often held, only or even mainly against the sanctity of womanhood. Infants and venerable woman are attacked; "the wanton murders and deadly assaults committed with steadily increasing frequency under circumstances of absolutely fiendish savagery; the abandoned recklessness of consequences and the astounding indifference to the sufferings of either themselves or their victims"[1] — it is such things as these which now require to be considered. And so frightful have they become, transcending, as we have noted, all previous experience of the negro race, that many cannot credit the accounts of them. Yet the facts are abundantly testified to by men experienced in observing the negro working in gangs, and in pursuits other than agricultural.

A possible explanation of these phenomena lies in cocainism, particularly when combined with alcoholism. We know that gentle, cultivated and ordinarily well-poised individuals of the more highly organized white race are stimulated by cocaine to acts of violence due to the hallucinations induced by its use. How, then, can we expect otherwise than that an illiterate negro, living in a semi-barbarous environment, and unaccustomed to social discipline, will, when excited by this drug, become even more uncontrolled? There is good reason to suppose that cocaine is furnished the negro in such industrial settlements as we have mentioned. "An official of one of the largest drug houses south of New York says that his firm ships enormous quantities of the drug to all parts of this section of the country. The orders come from contractors and operators of the most extensive kind, and these say that they could not keep their working forces together for so much as a week if the men were unable to procure cocaine in the immediate vicinity."[2]

The National Association of Negro Physicians, Dentists and Pharmacists met recently in Baltimore. Its membership is made up of about three hundred among the two thousand negroes who are practising in this country; and every member holds a degree from some reputable medical college — Harvard, Yale, Columbia, the University of Pennsylvania and the like. These man are making a fight (though one most unfairly put upon them) for the eradication of cocainism, with its attendant evils—alcoholism, syphilis, and tuberculosis—from among their unhappy fellows; and it is for the profession at large to hold up their hands.

MEDICAL NOTES.

Health in the Canal Zone. — It is reported from Washington that very great improvement has taken place in the sanitary conditions in the Canal Zone, with a corresponding reduction of illness among the canal workmen. With ten thousand more men at work, there are fewer sick this year than there were last. From the statements made it appears that the authorities have in hand the problems of sanitation, which at first appeared a menace to the successful prosecution of the work.

Pneumonia in Chicago. — According to the *Bulletin of the Chicago Department of Health*, for the first eight months of the year, the records of the Bureau of Vital Statistics show an increase in the reported deaths from pneumonia of one third (33.6%) over the number reported during the corresponding period of 1906. The increase of August, 1907, over August, 1906, is 43.1%, while the increase of the week of Aug. 31, 1907, over the number of the corresponding week of last year is nearly double (96.3%), that is, 27 in the 1906 week, and 53 in the 1907 week.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Sept. 25, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 46, scarlatina 47, typhoid fever 40, measles 68, tuberculosis 69, smallpox 1.

The death-rate of the reported deaths for the week ending Sept. 25, 1907, was 18.91.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Sept. 21, 1907,

was 217, against 235 the corresponding week of last year, showing a decrease of 18 deaths and making the death-rate for the week 18.57. Of this number 115 were males and 102 were females; 210 were white and 7 colored; 128 were born in the United States, 84 in foreign countries and 5 unknown; 40 were of American parentage, 145 of foreign parentage and 32 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 33 cases and 4 deaths; scarlatina, 36 cases and 0 deaths; typhoid fever, 45 cases and 1 death; measles, 9 cases and 0 deaths; tuberculosis, 62 cases and 21 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 14, whooping cough 1, heart disease 20, bronchitis 1 and marasmus 12. There were 20 deaths from violent causes. The number of children who died under one year was 60; the number under five years, 76. The number of persons who died over sixty years of age was 45. The deaths in public institutions were 77.

There was 3 cases and 0 death reported from cerebrospinal meningitis during the week.

PRESIDENT OF THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION. — Dr. Herbert F. Pitcher, of Haverhill, Mass., has been elected president of the American Electro-Therapeutic Association, which has recently been holding its annual meeting in Boston.

NEW HAMPSHIRE MEMORIAL HOSPITAL. — The tenth annual meeting of the New Hampshire Memorial Hospital in Concord, N. H., was held Sept. 11. This hospital was built to the memory of Dr. Julia Wallace Russell, and is devoted to the care of women and children. During the ten years of its existence it has ministered to a large number of persons unable to pay for medical attendance. Changes have been made in the hospital to meet the increasing demands upon it.

DIPHTHERIA AT APPONAUG, R. I. — Many cases of diphtheria have recently appeared in the village of Apponaug, R. I. It is an interesting fact that most of the cases have developed in the neighborhood of a trench running through the center of the village which received much waste during the recent rains. It is furthermore interesting that most of the cases are adults.

WORK OF THE NURSES IN THE PUBLIC SCHOOLS. — The newly appointed nurses for public school inspection have already demonstrated their usefulness by reporting various affections which need dispensary or hospital care. The question has arisen whether it is wise to make these reports public in the newspapers, thereby possibly exciting unnecessary alarm.

NEW YORK.

PHYSICAL CONDITION OF PUBLIC SCHOOL CHILDREN. — As a result of the recent agitation concerning the physical condition of public school children, the Board of Education is contemplating the establishment of a separate department of school hygiene, the province of which will be to act in an advisory capacity on all matters relating to the health of the pupils and to recommend safeguards for the protection of their physical welfare. Notwithstanding the work that is now being done by the Health Department in connection with the public schools, the estimated cost of putting the proposed new department in operation is at least $30,000, but the school commissioners feel that the results obtained would amply justify such outlay and also that the expenditure would be generally approved by the taxpayers.

DUST AS A CARRIER OF DISEASE AMONG SCHOOL CHILDREN. — In his recent annual report, Lyman A. Best, president of the Brooklyn Teachers' Association, gives the result of an exhaustive investigation which he has made as to the agency of dust as a carrier of disease among school children, and furthermore shows that the use of the feather duster is largely responsible for the prevalence of the various contagious diseases. An examination was made of the records of the Health Department from 1898, when the Greater City of New York was formed, to July 1, 1907, as regards the ordinary contagious diseases of childhood, such as measles, scarlet fever and diphtheria. This revealed the fact that an abrupt rise in the number of cases of these affections occurs in the autumn, after school opens and the windows are closed, while just as abrupt a drop occurs in the spring, when the windows are opened again. The decrease continues to a minimum in September, the maximum occurring six months later, in March. "What is the cause?" continues the report. "Dirt! schoolroom dust! Any one who has watched a janitor moving in a cloud of dust as he passes through the halls and schoolrooms after school, and who will note the layer of dust that settles over the floors, furniture and side walls after he has finished sweeping, will not wonder any further how the germs get mixed and distributed." Mr. Best then compares conditions in New York with those in Worcester, Mass.,

where sanitary methods of cleaning schoolrooms have been adopted. During the period from Jan. 1, 1898, to July 1, 1907, there have been reported 2,834 cases of measles in Worcester. The number of cases in New York for the same period, population reduced to the Worcester standard, was 6,432, or more than twice as many. In the case of scarlet fever and diphtheria the proportion of cases in New York in excess of the cases in Worcester was about 25%. Among the remedies suggested are the following: All feather dusters should be destroyed and their further use prohibited. Before any sweeping is done, wet sawdust should be scattered over the floor. Dusting should be done with dampened cloths. Every schoolhouse to be erected in the future should be provided with a complete vacuum outfit, with proper connections in every room of the building. "If, through the adoption of proper methods in cleaning," the report goes on to say, "the death-rate should be decreased by 1% for measles, scarlet fever and diphtheria, and if but one half the cases of these diseases are among school children, there would be a saving of life in New York of 85 school children a year who now die from measles, 53 from scarlet fever and 71 from diphtheria; 209 school children in all, and a total for the city of 418. Had the mortality rate in New York City for the three diseases discussed in this report been the same as in Worcester for the nine and a half years under consideration, the saving of lives in New York from these three diseases for that time would have been: 482 from measles, 2,760 from scarlet fever and 7,884 from diphtheria and croup, a total of 11,126, giving an average of 1,171 a year, or more than three lives a day."

Clean Milk. — The New York City Health Department having formulated certain regulations to insure the production of clean milk at the dairy, and having announced that unless these are complied with within a specified time no producer thus failing to remedy the conditions of his premises will be permitted to send his milk to the city, some of the farmers in certain parts of the state have raised a protest against the exaction of the rules as being too stringent. As a matter of fact, however, what the Health Department demands, as has been well said, is simply what an intelligent, up-to-date dairyman, eager to conduct his business in the best manner and to make the most of it, would do of his own accord in order to increase the returns on his capital and labor. Indeed, it is what the up-to-date dairyman has already done without any compulsion and he has had his reward in the shape of healthy herds and higher prices for his products.

A Death from Fright. — A death from fright, incident to an unusually loud clap of thunder, is reported from Mount Vernon, Westchester County. The patient was an old lady, seventy-five years of age, and her death was instantaneous. The predisposing cause is not given.

Epidemic Poliomyelitis. — Epidemic poliomyelitis continues prevalent, and it is stated that more than four hundred cases have been brought to the Hospital for Ruptured and Crippled for treatment. Dr. A. B. Judson, the well-known orthopedist, is authority for the statement that, as the result of observations at the out-patient department of the New York Hospital, it is believed that the deformity and lameness which follow an attack of this disease may be largely prevented by keeping the patient, after the fever has subsided, in a recumbent posture (or at all events off his feet) for eighteen months. This is not an easy thing to do when the child should naturally be learning to walk, especially as it is the common belief that exercise is more important for such a case than anything else. The reason, he says, is found in the fact that there is a spontaneous diminution of the paralysis for several months, and to make the muscles of the lower extremities do the work of carrying the body prevents them from sharing in the recovery which goes on without interference in the arms and hands, which are exempt from effort and strain. It has been noticed that the permanent paralysis and deformity are common in the lower and almost entirely absent from the upper extremities. The customary treatment for paralyzed limbs may be continued while the patient is recumbent.

5. Rosenbeck, C. *The Early Recognition of Tabes Dorsalis.*

1. Whitman brings forward a theory of the causation of weak foot, which will account for the discomfort without deformity that is often found in this condition and a treatment that is applicable to the prevention of the condition

before advanced distortion has occurred. There are two contrasting postures of the foot,— that of activity and that of inactivity. In activity the foot is incurved at the inner border and the arch is accentuated. In inactivity the foot is everted and the weight is directed toward the inner side of the sole. The abnormal persistence of the attitude of inactivity during exercise produces deformity. Abduction is caused by inward rotation of the leg upon the foot, and the astragalus supporting the leg sinks downward and inward upon the os calcis. Acquired flat foot and weak foot are an abnormal persistence of the attitude of abduction. The primary factor is the abduction, the secondary is the lowering of the arch. The symptoms are due to overstrain and injury to which disordered function has exposed the foot. Predisposing causes are insufficient support, due to congenital or acquired weakness of structure, weakness of muscles, overweight or strain and improper attitudes. Improper attitudes include toeing out, the most important bad attitude. Improper shoes are often worn. Rachitis is a cause of weakness of structure. Symptoms include bad attitude, weakness, pain in feet, knees and even back, and deformity with muscular spasm. Preventive treatment includes proper shoes and proper attitudes for children. Shoes should turn in. The brace used is made on an accurate plaster model made with the foot resting upon the outer border, slightly plantarflexed and perpendicular to the table. The brace is of sheet steel extending from the bearing surface of the heel to the metatarsal bone. It is placed in the shoe, and the inner flange is pressed against the arch in positions of strain. It should hold the foot in place without discomfort. The inner side of the shoe is raised. Deformity may need to be corrected with or without anesthesia.

3. Solis-Cohen reports six cases, all obscure, in which the diagnosis was only possible by finding tubercle bacilli in the feces. The technique is essentially that employed in sputum examination. None of these cases presented the typical picture of intestinal tuberculosis. In the one case which came to autopsy, a case of miliary tuberculosis, there were no lesions of the intestinal mucosa. There were pulmonary signs in five, but in none were tubercle bacilli present in the sputum. The writer urges the value of the examination of feces for tubercle bacilli in obscure cases and in early pulmonary tuberculosis when the sputum is either absent or negative. The necessity of the disinfection of feces in all cases of tuberculosis is obvious.

2. Park considers that the danger of typhoid infection from ice is at best very slight and is quite negligible after the ice has been kept for six months.

10. Pratt gives the history of the first tuberculosis class of Emmanuel Church, Boston, the plan and methods of which were thoroughly described by Drs. Hawes and Floyd. Excluding present members of the class, there have been 37 members; 13 of these were far advanced cases, but 3 of these patients recovered. Of the remaining 24, 15 were moderately advanced cases, and in 9 of these the disease had been arrested. The remaining 9 were incipient cases, and of these 7 were apparently cured, and in the other 2 the disease was arrested. The expenses up to May 1, 1907, were about $2,000. The chief factors in the success of the class are given as follows: (1) The patients have spent the nights as well as the days out of doors; (2) they have been kept at rest in the recumbent position, not only until their temperature is normal, but until the symptoms of active disease have disappeared; (3) the system of daily records devised by Dr. C. L. Minor; (4) the weekly meeting. Implicit obedience of rules and regulations is required. Pratt gives details of the methods employed and illustrates the tents and other appliances for rest with open-air treatment.

14. The pelvic articulations are true joints and undergo definite motions, irrespective of sex. In women, during menstruation and more particularly during pregnancy, there is relaxation of these articulations. As joints, the pelvic articulations are liable to the same disturbances as other joints. Inasmuch as their stability depends on the tone and character of the muscles and ligaments, these articulations, more especially the sacro-iliac joints, are liable to strains and partial luxations. Lesions of the sacro-iliac joints are often complicated by lesions of a similar character in the spine. The common symptoms are limitation of motion and pain, usually in the sacral region, and often referred to leg or thigh, due to strain or irritation of the nerve trunks. Swelling is uncommon. The most characteristic sign is the fact that when the patient lies on his back, the hip motions are free as long as the knee is flexed. If the knee be straightened and thigh flexion attempted, then there is limitation and often pain referred to the sacro-iliac joint. This is due to the fact that the hamstrings, being stretched, pull on the ischium and cause motion of the joint. The treatment, depending on the character of the lesion, is usually by various supports, exercises, etc.

15. White has found numerous spirochetes closely resembling the spirocheta pallida in the glands of two apparently undoubted cases of Hodgkin's disease.

1. Berry divides all cases of peritonitis into four classes for purposes of treatment: (1) A simple, beginning peritonitis with no perforation of any viscus in which he believes in free purgation and salines by rectum, subcutaneously or intravenously; (2) where there has been a recent perforation, in which case immediate operation is necessary to close the perforation; (3) a later stage, in which there is considerable peritonitis with tendency to localize more or less in one region. In many of these cases Berry thinks an immediate operation does a great deal of harm. Purgatives, food by mouth or large enemata should not be given, and operation should be withheld until the condition is as well localized as possible. (4) Cases in which there is a general diffuse peritonitis over all or a large part of the abdomen. For all but the very worst cases he advises the Ochsner method; for the worst cases he considers the method advocated by Murphy the best, *i. e.*, a small wound, closing the perforation, a large drainage tube to the pelvis and the patient propped up in bed at an angle of 35° or more.

2. Campbell-Horsfall reports in detail a case of acute yellow atrophy of the liver with a table of eleven other cases reported up to date.

4. The writers give this case in full, as they have been unable to find a record of a similar instance of infection due to the influenza bacillus. Their patient was a girl ten months old. The infection was first localized in the right elbow and then the right hip-joint. Meningitis then supervened and death followed. Film preparations and cultures from blood and pus showed a pure culture of the influenza bacillus.

5. Charteris summarizes his observations on a man who fasted for fourteen days, as follows: The pulse slowed gradually as the fast proceeded; arterial pressure sank to 25% of the normal; the hemoglobin remained steady at first, but later changed rapidly; the red corpuscles did not vary except that at the end a few nucleated reds were found. There was a slight leucocytosis. The opsonic power showed no alteration.

1. Helme considers the important subject of the care and rights of the unborn child in a thorough, careful and scientific way. The agencies of late years being brought to bear to prevent infant mortality are not used soon enough, but should be brought into play before the child is born. He considers briefly the subjects of fetal mortality and morbidity; the value of fetal life; diminution of birth-rate and its causes; and certain factors affecting the unborn child, such as food, its quality and quantity, especially the latter, stating that in his experience pregnant mothers eat far too much. Drugs, alcohol, mode of life and work are all considered.

4. Spencer, in order that uterine cancer may be earlier recognized, advises the diffusion of knowledge among women of twenty-five years and over as to its first signs and symptoms, and that all practitioners should make a careful examination, microscopic if possible, of all growths and tumors of that region. Frank speaking was urged in every case of trouble in the pelvis which might be malignant.

2. In twenty cases of pneumonia Rennie has used outdoor treatment. There were but two deaths. He believes that this treatment has a distinctly beneficial effect on all the symptoms, especially on the pulse. Sleep is easier to obtain and cyanosis greatly decreased.

3. Acland thinks that far too little attention is paid to sanitation and hygiene by school authorities and inspectors. The doctor in attendance treats the sick child but neglects the causes underlying its illness. Bad food, too little sleep, too much study, are all large factors in preventing healthy development of growing boys. Various examples of deplorable conditions are given and remedies suggested. The remarks only apply to conditions in England.

8. Bassett-Smith believes that aneurysms are especially frequent in the navy. During seven years at the Haslar Hospital there have been 47 cases, of which 37 were thoracic, while 10 were abdominal. The majority were found in men who worked in the engine-room. He has been unable to find evidence that in this series either syphilis or alcohol played a very large part.

8. *BÖCKER, W. *Paralytic Luxation of the Hip-Joint.* (Concluded.)

1. In a previous communication, summarized in these columns (*Deut. med. Wochenschr.*, No. 23), von Leyden showed the specific action of fresh liver ferment upon carcinoma. Bier, in the present article, reports a similar action, when the blood of a different species is injected in the neighborhood of the cancer. If 10 to 20 cm. of defibrinated swine's blood be injected subcutaneously under aseptic precautions, a very striking local reaction is set up, with fever and often chills. This subsides after three or four days and by repeating in greater or less amounts, the severity of the reaction can be more or less controlled. He asserts that a large carcinoma of the face, after four injections, became converted into a firm scar through the intense inflammatory infiltration and connective tissue growth. Another cancer of the neck under the influence of the enzyme broke down in rapid necrosis and subsequently healed. Other cases were apparently influenced. He also used these injections in 3 cases of benign hypertrophy of the prostate with retention of urine, with apparently beneficial results. That we shall ever be able to control the growth of malignant tumors by this or similar methods, Bier thinks is extremely doubtful, but the subject is full of interest and needs thorough investigation.

4. Since the use of fat in test meals for the determination of motility was first proposed by Matthieu in 1896, it has been open to many objections. Strauss thinks he has overcome these by employing, as the fat-containing agent, a cracker made up in pieces of 50 gm. each, having a fat content of 10.6% butter and 5.3% milk fat. This has an agreeable taste, keeps a long time and has a constant fat content. He gives it with 400 cc. of tea and one hour after ingestion removes the contents in three parts: (1) the expressed contents, (2) the washing after the introduction of 100 cc. of water, and (3) after washing with several liters. For the determination of fat the authors prefer the refractrometric method of Wollny instead of the more complex Gerber's butyrometric method, as it gives equally exact results, and the necessary refractrometer is an instrument which should be in every laboratory. Experience with this method has already shown that stomach disturbances are decidedly more complicated than has hitherto been imagined. By it, one can decide whether an increase in the amount of the expressed contents points to an hypersecretion or to a motor disturbance, and discriminate more exactly than before between hypersecretion and hypo-acidity, since the volume of secretion as well as the acidity of the pure gastric juice can be calculated.

8. Böcker concludes that the spinal paralyses of children often go on to a paralytic luxation of the hip-joint, and that as a cause the antagonistic muscle theory of Seeligmuller holds good to-day. The x-ray shows backward displacement more often than is commonly supposed, while luxation forwards, as shown by typical abduction, contractures and palpation of the head of the femur under the horizontal part of the pubic bone, is often a subluxation. True luxation proved by the x-ray is comparatively rare. Prophylactic treatment to prevent contractures is of the greatest importance. If contractures have occurred, tenotomy in early cases, operation and cutting of contracted muscles, forcible replacement and holding position with plaster bandages, give the best results.

1. The importance of a normal standard in the diagnosis of conditions depending upon anomalies in the secretion of the gastric juice is evident. The author was able to observe the character of the stomach secretion in a young girl, who suffered from a fistula following a benign stricture of the esophagus. His results are similar, in the main, to those of Pawlow, who used dogs with artificially induced esophageal fistulæ. He states that pure, normal gastric contents (a mixture of pure gastric juice, food saliva, and alkaline mucus) contains two or three times as much HCl as is usually supposed, being 0.4 to 0.55%. This acid content remains remarkably constant during a secretion period. As a classification is necessary for intelligent treatment the author divides cases of supersecretion, according as it is confined to the digestive period or is continuous. He finds with Pawlow that psychic, chemical, and mechanical stimuli are of the utmost importance in increasing the flow of the gastric juice, and in any treatment of hyperchlorhydria these should be strictly eliminated. Drugs are of little use. Alkalies and mineral waters may be used freely. The alkalies available for this purpose are the carbonates of sodium, calcium, and magnesium. The chief reason for selecting one or the other of these remedies is their effect upon the intestine, the magnesium salts being laxative, and the soda having no effect. They all tend to diminish the secretion of acid, while proteid food, especially meat, tends to increase it. Therefore they should be given on an empty stomach.

3. Muhlens has experimented by rubbing into the skin of rabbits the expressed juice from lungs, suprarenals, and liver of a one and one-half-hour old child, dying of congenital lues. With this fresh juice, in which the spirocheta pallida was proven present, he was able to produce a keratitis parenchymatosa of syphilitic origin.

4. Plehn describes a case in which, four weeks after the cure of a Blackwater fever, contracted in West Africa and showing typical malarial organisms, a benign tertian infection developed while the patient was in Germany. He claims this is an illustration of how one form of the malarial parasite may change into another through change of climate. [L. G. M.]

7. MAYER, A. *The Presence of Bile Acids in Human Milk.*
8. *MOHR, L. *Pathology and Treatment of Certain Forms of Emphysema of the Lungs.*

1. Aufrecht has shown that the earliest tuberculous changes at the apices do not arise from the infection in the small bronchi, but the primary tubercles are always in close relation with the small arteries and the capillaries. It is possible, as has been shown by serial sections, for tubercle bacilli to pass through the walls of these small vessels into the surrounding tissues. The portal of entry for the bacilli which is by far the most common is the tonsils; then the glands of the neck or the mediastinum becomes infected, and from these seats of infection, the blood vessels carry the bacilli to the apices of the lungs. The author thinks infection through the lymph channels is very rare. He considers the theory of infection by inhalation as untenable.

8. Mohr says that besides ordinary emphysema of the lungs due to increased difficulty in inspiration or expiration (chronic bronchitis, bronchial asthma, etc.) there is

a group of cases, due primarily to fixation of the ribs by stiffening or actual calcification of the costal cartilages. He has noted numerous cases, and also refers to Freund's series. In these cases there is but little movement possible during breathing, and the expiratory contraction does not exist. In a few cases resection of small portions of the calcified costal cartilages has been followed by a return of the movement during respiration. with a marked improvement in dyspnea, and disappearance of cough and bronchitis. [R. D.]

2. Magnus demonstrated Nothnagel's theory that morphin exerted its action on the intestine through the sympathetic system to be mistaken. Having cut the sympathetic nerves carefully, after the recovery of the animals, large doses of morphin worked as well as in normal animals. In a series of experiments on cats and dogs who had been given large doses of bismuth mixed with food and then observed with the fluoroscope, Magnus found that after doses of morphin food remained in the stomach from three and one half to eight hours, and that owing to a constant contraction of the sphincter antri, came only very slowly into the pyloric portion of the stomach. The peristalsis was unchanged. On dogs, with duodenal fistulæ, it was found that the food passing from stomach into intestine, under the influence of morphin, was very much more finely divided than normal. These observations point to a lengthening of the period of gastric digestion under morphin, and also to an increase in the digestion of the food in the stomach. The time for the food to pass the small intestine was also much prolonged, but in no way could it be demonstrated that the large intestine was affected by the drug.

3. Very valuable data can be obtained by the x-ray examination of the stomach and intestines, after the administration of a "bismuth meal." The size, shape and position can be more accurately judged in this way than in any other. The question of motility is easily settled by timing the disappearance of the shadow from the stomach. Any shadow remaining after three hours may be considered as abnormal. The secretory functions of the stomach may also be judged in this way. A small dose of bismuth is put up in a capsule of goldbeater's skin,which is digested in a longer or shorter time by the gastric juice. The bismuth which at first appeared as a small round shadow is liberated and appears as an irregular cloud. The time taken for this reaction will give an idea as to the condition; *i. e.*, one and one-half hours when hyperacidity is present, two and one-half hours under normal conditions and five hours or more for anacidity. Chemical controls have shown the above method to be trustworthy. In ulcer of the stomach, the ulcerated area may be located by the bismuth which adheres to its surface. This is by no means a constant occurrence. In regard to intestinal diagnosis, this method tells little about the condition of the small intestine. Useful data as to the position of the large intestine (ptosis, etc.) may be obtained and, in favorable cases, stenosis may be localized. In conjunction with other methods of diagnosis the author recommends this procedure very highly as many valuable points may be gained thereby.

5. Mandelbaum treated twenty-four-hour bouillon cultures of pneumococcus, streptococcus, mucosus and other streptococci with 2 cc. of 10% solution of sodium taurocholate. After shaking the mixtures, he found that cultures of pneumococcus, streptococcus and mucosus were clear, bright and transparent, the other streptococci cultures were still cloudy. Cultures from all the above were sterile. In hanging drop preparations, not a trace of pneumococcus or streptococcus mucosus was to be seen, but when these preparations were stained with methylene blue and examined with the oil immersion fairly numerous involution and degenerative forms were to be seen. The same result as the above was obtained by using oxgall instead of sodium taurocholate. The latter is hard to obtain, must be freshly made, and is expensive.

[R. D.]

REVUE DE CHIRURGIE.
JULY, 1907.

1. POIRIER, P., AND PICQUÉ, R. *Surgical Anatomy of the Hyo-thyro-epiglottic Region.*
2. *JEANBRAU, É., AND ANGLADA, J. *Trauma and Appendicitis; a Pathological and Medico-Legal Study.*
3. *CORBELLINI. E. J. *The Radical Cure of Inguinal Hernia.*
4. *QUÉNU, E. *Separation of the Inferior Tibio-Fibular Joint.*
5. GUIBÉ, M. *Volvulus of the Small Intestine and of the First Part of the Large Intestine.*
6. BAUMGARTNER, A., AND HUGUIER, A. *Sub-astragaloid Dislocation of the Foot.* (Continued article.)

2. As a result of an interesting study which the authors have made concerning the rôle which trauma may play in causing appendicitis, the following facts are brought out: (1) In an individual whose appendix is healthy and contains no foreign body, a blow on the abdomen or a violent effort cannot call forth appendicitis. (2) In a person having had attacks of appendicitis, or in one suffering from latent appendicitis,such a blow, even though it be a considerable distance away from the ileo-cecal region, can light up the chronic inflammation and cause an acute attack, with perforation, and even death. (3) In one suffering from latent appendicitis an effort such as a fall on to the feet, by rupture of adhesions, can bring about the same result. (4) If pain and signs of peritonitis do not occur till after forty-eight hours from the time of the accident, this cannot be held responsible for the attack. (5) If the patient, having recovered from the attack caused by the trauma, has still further attacks, these cannot be imputed to the original trauma. The application of these facts in accordance with the law of 1898 regarding accidents to working men (Employers' Liability) is considered.

3. Corbellini considers it wrong to operate on all inguinal herniæ according to a single method. He divides herniæ of moderate size into (*a*) retro-inguinal and (*b*) intra-inguinal. In the first he advises repair of the posterior wall, leaving intact the anterior wall, and internal ring. In the second he repairs only the anterior wall, narrowing the canal and the external ring.

4. Quénu states that separation of the inferior tibio-fibular articulation is not peculiar to any one form of fracture. It can occur in conjunction with (*a*) fracture of the fibula in its upper quarter; (*b*) with Dupuytren's fracture (practically the same as Pott's fracture); (*c*) with a fracture of the extreme lower end of the fibula; (*d*) with a fracture of the internal malleolus; (*e*) with an oblique fracture of the lower quarter of the tibia; or, (*f*) perhaps, even when fracture is absent. It most often accompanies Dupuytren's fracture. The mechanism by which it is caused is an abduction of the toe with internal rotation of the sole of the foot. The prognosis of a fracture complicated by such separation should be a guarded one. In all fractures of the lower quarter of the tibia or fibula such separation should be looked for in the x-ray plates, and proper means taken for its immediate reduction, as the function of the ankle is considerably impaired if the condition is allowed to persist.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING SEPT. 21, 1907.

F. E. CAMPBELL, passed assistant surgeon. Detached from the "Washington," ordered home, resignation accepted to take effect Oct. 1, 1907.

A. B. CLIFFORD, assistant surgeon. Orders of June 17 revoked; detached from the "Maryland," and ordered to the Naval Hospital, Mare Island, Cal.

D. C. CATHER, assistant surgeon. Detached from the "Pennsylvania," and ordered to the Naval Training Station, San Francisco, Cal.

F. L. PLEADWELL, surgeon. Ordered to the Bureau of Medicine and Surgery, Navy Department.

K. OHNESORG, passed assistant surgeon. Detached from the "Wabash" and ordered to the Naval Hospital, Philadelphia, Pa.

J. L. BELKNAP, assistant surgeon. Detached from duty with the Marine detachment, Camp Harrington, Va., and ordered to the "Wabash."

E. A. VICKERY, assistant surgeon. Ordered to the Naval Hospital, Boston, Mass.

J. COWAN, pharmacist retired. Detached from the Naval Recruiting Station, New York, N. Y., and ordered home.

W. S. HOEN, passed assistant surgeon. Ordered to additional duty with Recruiting Party, No. 1.

H. E. AMES, medical inspector. Detached from duty on board the "Connecticut" as fleet surgeon of the Atlantic Fleet, and ordered to command the Naval Hospital, Boston, Mass.

N. T. MCLEAN, assistant surgeon. Detached from the Naval Hospital, Washington, D. C., and ordered to the Naval Station, New Orleans, La., Sept. 25.

C. T. GRAYSON, assistant surgeon. Detached from the Bureau of Medicine and Surgery, Navy Department, and ordered to the Navy Yard, Washington, D. C.

The following assistant surgeons and acting assistant surgeons have been ordered to report for course of instruction at the Naval Medical School, Washington, D. C., Sept. 30, 1907: Assistant Surgeons, M. E. ROSE, W. H. SHORT, H. L. KELLY, M. A. STUART; Acting Assistant Surgeons, S. BACON, C. W. O. BUNKER, C. J. HOLEMAN.

RECENT DEATHS.

DR. FELIX NORDEMANN, one of the best known foreign practitioners in New York, died of cardiac disease on Sept. 15. He was born in Berne, Switzerland, in 1828, and received the degree of M.D. from the University of Berne in 1853. He was one of the founders, in 1860, of the German Medical Society of New York, which is now one of the largest and most flourishing societies in the city. Dr. Nordemann was an esteemed adviser in the early days of the municipal hospitals, and during his entire practice he devoted much attention to the welfare of the poor children of the East Side.

DR. GEORGE NEWBY, a retired physician of New York, died at Sanford Hall, a private sanatorium at Flushing, Borough of Queens, on Sept. 19. He was a native of England, and eighty-seven years of age, and was graduated from the Royal College of Surgeons, London, in 1846. He took much interest in civic affairs, and is especially remembered for good service during early cholera epidemics. For some years he was one of the directors of the Metropolitan Museum of Art.

DR. CHARLES BURR BRIDGHAM, M.M.S.S., died in Cohasset, Sept. 17, 1907, aged sixty-six. He was graduated from Bowdoin Medical College and later served in the Civil War. He was entrusted with the delivery to his wife of personal effects of Col. Robert G. Shaw who was killed while leading a charge of colored troops at Fort Wagner. Since the war Dr. Bridgham has been a well known physician in towns along the South Shore of Massachusetts Bay.

BOOKS AND PAMPHLETS RECEIVED.

A Manual of Hygiene and Sanitation. By Seneca Egbert, A.M., M.D. Fourth edition, enlarged and thoroughly revised. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1907.

The Climatic Treatment of Children. By Frederick L. Wachenheim, M.D. New York: Rebman Co. 1907.

The Principles and Practice of Modern Surgery. By Roswell Park, A.M., M.D., LL.D. (Yale). Illustrated. Philadelphia and New York: Lea Brothers & Co. 1907.

Insanity and Allied Neuroses. A Practical and Clinical Manual. By George H. Savage, M.D., F.R.C.P., with the assistance of Edwin Goodall, M.D. (Lond.), B.S., F.R.C.P. New and enlarged edition. Illustrated. Chicago: W. T. Keener & Co. 1907.

Tracheo-Bronchoscopy, Esophagoscopy and Gastroscopy. By Chevalier Jackson, M.D. Illustrated. St. Louis: The Laryngoscope Co. 1907.

THE TREATMENT OF TYPHOID FEVER WITH SPECIFIC SERA, FILTRATES AND RESIDUES (VAUGHAN).*

BY MARK W. RICHARDSON, M.D., BOSTON.

It is now eight years since the writer first took up the study of immunity in typhoid fever with the avowed purpose of developing, if possible, an effective, specific method of treatment for the disease.

Invaluable aid in the production of a specific serum was furnished by the State Board of Health, which put at my disposal its stable for the care and inoculation of horses. Finally, to Prof. Theobald Smith I desire to express my deep appreciation of his continued interest and encouragement.

From unavoidable circumstances the work has been carried on spasmodically, and is in many ways incomplete. It has been pursued along the broadest of lines. The finer problems of immunity have been left untouched. Briefly expressed,

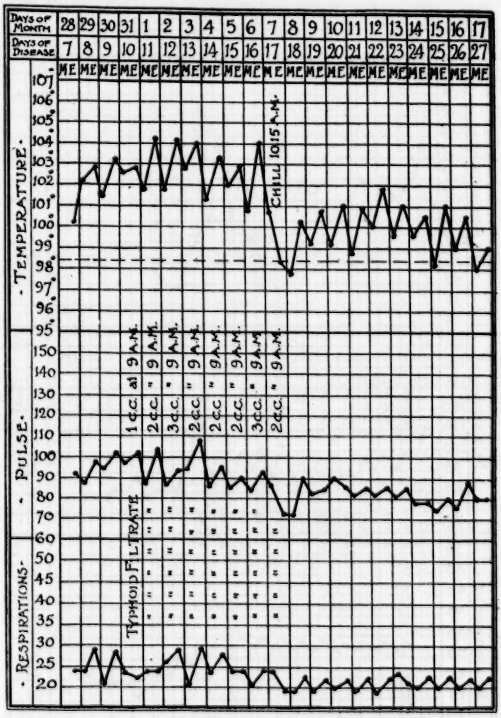

CHART 1.

Financially, the study has been supported by two grants of the Dalton Scholarship at the Massachusetts General Hospital.

For clinical material I am indebted for all but two cases to members of the Medical Staff at the same institution, and especially to Drs. Shattuck, Cutler and Minot. One case was referred to me by Dr. Arthur Broughton, of Jamaica Plain, and another by Dr. H. V. Reynolds, of Dorchester.

* Read at the Annual Meeting of The Massachusetts Medical Society, June 11, 1907.

the effort has been made, first, by inoculating the horse with typhoid material, to produce a serum which should be of assistance in human typhoid infection; and in the second place by inoculation of the typhoid patient himself with small doses of typhoid material to hasten his own immunity and cure. The latter method is, of course, similar to that of specific inoculation introduced recently by Sir A. E. Wright for staphylococcus and other bacterial infections. Thus far no attempt has been made to control treatment by observation of the so-called "opsonic index" of the blood.

This study covers observations upon 130 cases of typhoid fever, treated (in addition to the routine hospital treatment) with the following specific fluids: Antityphoid serum was used in 35 cases, and was produced by inoculating horses over a period of one to two years with gradually increasing doses of dead typhoid bouillon cultures. The serum of the horses was then given to typhoid patients (*a*) subcutaneously (5 cases in daily doses of 10 to 100 cc.); (*b*) by mouth or rectum or both (18 cases — dose, 100 to 1,000 cc. daily); (*c*) in pill form with special enteric coating (7 cases); (*d*) 5 cases subcutaneously with equal amounts of normal serum (15 cc. of each daily), to secure assistance of any complements which might be present in the normal serum. It was hoped that serum given thus in unusual method and dose might produce better results than had been previously obtained.

In a second series, 74 in number, a typhoid filtrate was used, always subcutaneously. This filtrate was obtained by passing living bouillon cultures through porcelain filters. The age of the cultures varied from two days to six weeks. The results obtained seemed to be the same, whatever the age of the culture. The dose averaged 3 cc. daily.

In a third series 21 cases were treated with "nontoxic residue" of the typhoid bacillus as prepared by Prof. Victor C. Vaughan, of Ann Arbor, and kindly sent to me by him (daily subcutaneous dose, 2 to 10 cc.). This residue, though nonpoisonous, contains all the essential immunizing portions of the typhoid organism.

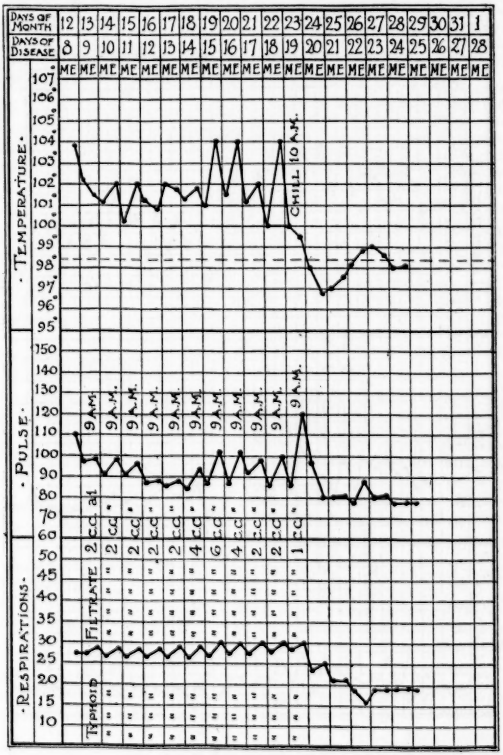

CHART 2.

Finally, in a series of 28 cases (6 of which are already included in series 3) it was attempted to prevent relapses in typhoid fever by the continued inoculation of the nontoxic residue at increasing intervals during convalescence.

Now, in any consideration of specific therapy in typhoid fever it is important to bear in mind that we have to do with a problem involving not the simple neutralization of a toxin by an antitoxin, as in diphtheria, but having for its object the in-

creased destruction of the invading germ. This destruction follows the interaction of factors much more complex than those seen in diphtheritic infection, and, furthermore, means the setting free of whatever intracellular toxin those germs contain. Treatment along these lines, therefore, would not be appropriate for patients already severely intoxicated, but should, on the contrary, be inaugurated at the earliest possible stage of the disease.

consequent shortening of his disease. That is to say, we have tried to hasten and strengthen the active immunity natural to the disease by the introduction into the body of additional small doses of specific infectious material.

That these inoculations, therefore, should be effective and advisable from a therapeutic standpoint it is essential, first, that the patient be not so sick that he cannot react with greater efforts towards destruction of invading germs and, sec-

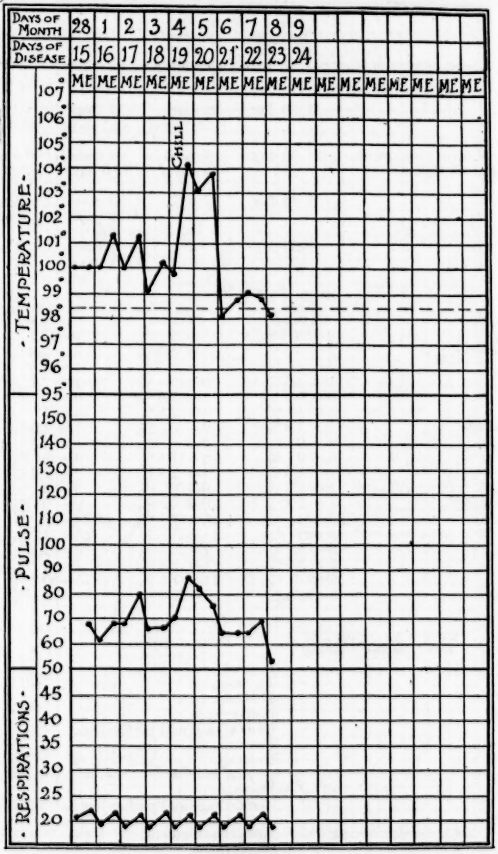

Chart 3.

With our serum, then, we have tried to introduce into the patient's body specific substances destructive to the typhoid bacillus, substances produced by inoculation in the blood and tissues of the horse. In other words, any immunity induced by this treatment is of the passive variety. With the filtrates and residues our object has been to stimulate the patient's own blood and tissues to greater production of specific antibodies, and the ond, that he can stand the temporary increased intoxication due to that destruction.

A comparative study of 130 cases of typhoid fever appears in the following tables, which offer many points of interest, but which must be scanned very critically lest they convey false impressions.

In the first place the percentage of children in any typhoid series is important because, as is well

TABLE I.

	Routine series.	Serum series.	Filtrate series.	Residue series.
No. of cases treated,	74	35	74	21
Cases 15 years of age or younger,	19	6	16	6
Average day of disease on entrance,	12.05	10.4	10.21	11.4
Average day of beginning treatment,	12.05	15.6	13.83	13.05
Treatment delayed, lack of diagnosis,	(20)	8	9	5
Average necessary delay,	(6)	4.25	8.88	5
Average length of fever in original disease,	67 cases	33 cases	63 cases	19 cases
	27.35	30.3	27.45	32.5
No. of days in hospital,	67 cases	33 cases	63 cases	19 cases
	31.77	45.75	41.57	42.42

TABLE II.

	Day of beginning treatment.	Routine treatment series.	Serum series.	Filtrate series.	Residue series.
Average length of fever subsequent to the beginning of treatment,	1–10 day	38 cases	9 cases	19 cases	8 cases
		16.55 days	15.8 days	11.15 days	19.37 days
	11–20 day	22 cases	17 cases	34 cases	8 cases
		17.26 days	16.1 days	13.64 days	20.75 days
	21–30 day	7 cases	4 cases	5 cases	2 cases
		12 days	10.5 days	18.6 days	9 days
	31–40 day	0	2 cases	1 case	0

known, the disease in children is apt to be mild in type under natural conditions.

(2) Typhoid patients rarely come under any form of treatment until the disease has been in progress several days. Hospital experience, as shown by 204 cases, makes the average day of entrance the eleventh day. This early period, moreover, most important for the inauguration of any specific treatment, is still further lengthened by the fact that, even at this stage, a positive diagnosis is often impossible.

(3) In 204 cases specific treatment could not have been begun immediately in 42 instances, and the average increased delay from that cause would have been five days. Until, therefore, earlier diagnosis becomes available, specific treatment must be severely handicapped. Table II would seem to bear out this contention, for in spite of delayed diagnosis and treatment, there was in the early cases an apparent shortening of the original fever in the serum and filtrate series.

In the residue series, however, the subsequent fever was apparently lengthened, and statistics thus strengthen what was my strong impression while the cases were under observation, namely, that these cases were drawn out, but on the other hand seemed unusually mild in character. The coincidence of increased length with increased mildness may be only apparent, but further experience may give it great importance. As to the average stay in the hospital, the cases under specific treatment stayed considerably longer, — due undoubtedly to the large percentage in those cases of relapses. One serum case, for instance, went through five relapses and was in the hospital 116 days.

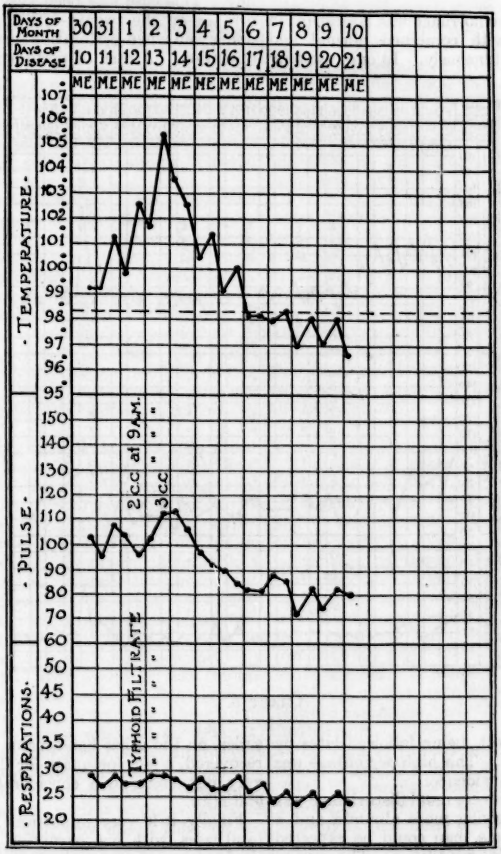

Chart 4.

The comparative frequency of complications appears in Table III.

Taken with the great reserve with which all such tables must be observed, we see that the impression of mildness in the residue series is further borne out.

The high percentage of diarrhea in the serum cases was due undoubtedly to the rectal administration of the remedy, and consequent irritability of the lower bowel.

The frequency of hemorrhage was largest (4) in the cases treated with combined normal and typhoid serum subcutaneously. In one case only and when the patient was apparently becoming rapidly convalescent. There was a similar case of embolism in the untreated series.

The case which died of pneumonia had practically finished a mild typhoid infection when double otitis media required etherization. Pneumonia and death supervened in four days.

A perforated appendix claimed a third case. Treatment was not begun till the thirty-second day. This case had been very severe with hemorrhage on the twenty-fifth day. The case was doing well when perforation demanded immediate operation. A case of perforation in the routine

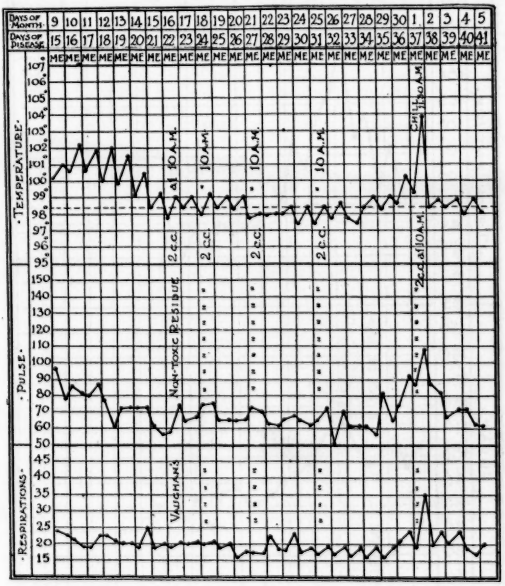

CHART 5.

was it of serious import, being followed later by perforation and death. This high percentage was probably simply a coincidence.

Under the head of severe renal disturbance was included all cases showing more albumin and a greater number of casts than could be expected from ordinary febrile conditions. The serum series shows apparently a very high percentage of kidney involvement, but close scrutiny shows that 4 of the 8 cases had this urinary condition before specific treatment was begun.

In studying the table of mortality (Table IV) one is struck immediately, of course, by the large mortality in the series of 74 filtrate cases as compared with 74 routine cases. This very unfavorable showing is very misleading, for in the first place the death from embolism occurred without warning nine days after inoculation had ceased, series, on the other hand, came to operation and recovered, a fact fortunate for the individual, but very disturbing in a consideration of mortality statistics.

Finally, it is very important to know that all fatal cases, with one exception (second perforation), were severely sick when they came under treatment, and the outlook in such cases, as we have seen, is not encouraging.

In the residue series the first fatal case, as proven during life and autopsy, was a mixed infection with the staphylococcus aureus. With our present knowledge this case would have received a mixed treatment of typhoid and staphylococcus vaccines, and might possibly have been saved.

Hemorrhage in typhoid, which claims so many victims, seems to be due, in part, at least, to a

faulty coagulability of the blood. It is not probable that antityphoid measures alone can materially affect mortality from this cause.

In this investigation certain phenomena have been observed which deserve mention.

In the serum series 1 case alone was marked by an unusual manifestation. A woman, moderately sick, had received subcutaneously for six days 100 cc. of antityphoid serum. On the seventh day, coincident with a very marked urticaria, the temperature fell suddenly, and her pulse became very weak. She was in a dangerous condition for twenty-four hours. The circulation then rapidly improved, in fact the clinical condition was better than before the occurrence. I ascribe it either to a sudden destruction of many typhoid bacilli with resulting hyperintoxication, or to some internal manifestation allied to the urticaria, and due to the same cause, namely, large amount of horse serum.

In the filtrate series, 29 cases were remarkable through the occurrence of quite characteristic reactions, namely, a chill coming almost always one hour after inoculation, and accompanied by a sharp rise in temperature, pulse and respiration. This increase in symptoms was followed in many instances by a marked decrease in the temperature and the pulse, and considerable improvement in the general condition of the patient. (See Chart 1.) After a short interval the temperature in most cases went up again, but in a few instances the temperature remained at normal permanently. (See Chart 2.)

This phenomenon, though rarely, is seen in the natural course of typhoid. (See Chart 3.) Tentatively I would explain it by supposing that ordinarily the destruction of typhoid bacilli with resulting toxin production takes place quite continuously, and sudden fluctuations in the intoxication are rare. Occasionally, however, under natural conditions, and especially under filtrate inoculation, destructive agencies are brought into sudden and excessive action with the resulting temporary increase in symptoms. This excess of action, as I take it, might well be followed temporarily by no action at all, and that would explain the fall in temperature and pulse. After a short interval the destructive apparatus would again take up its work, and the intoxication would go on (Chart 1) unless all the germs had been killed. In this case the temperature would remain normal, there being no further bacilli to furnish intracellular toxin. (Chart 2.) It may be possible to prove the truth or falsity of this theory by observation on the opsonic index before and after chill.

Another filtrate case was interesting because it shows very probably what might be accomplished in a majority of typhoid cases if they could but receive specific treatment very early in the disease. (See Chart 4.) This patient came in very mildly sick on the tenth day of the disease. Two inoculations with filtrates produced temporarily a marked increase in his symptoms, but this was followed immediately by a rapid and permanent convalescence. That these filtrates, furthermore, are anything but indifferent fluids I demonstrated on myself by a subcutaneous inoculation of 2 cc. For twenty-four hours I had fever, headache, backache, increased pulse-rate; in fact, all the common symptoms of an acute infection. Moreover, in three weeks my blood developed a faint but perfectly distinct typhoid reaction.

Finally, I have to record a series of 28 cases in which it was attempted to prevent relapses in typhoid. To accomplish this the patients were inoculated at increasing intervals during the convalescence with small doses (generally 2 cc.) of Vaughan's nontoxic residue.

In 28 cases there was one relapse. The incidence of relapse among the untreated cases during the same epidemic was 25 in 113 cases. That is to say, the percentage of relapses was reduced apparently from 22.1% to 3.57%. My strong impression that this gratifying result is real is reinforced by the behavior of some of the cases under inoculation.

For instance, in Chart 5, it is seen that four inoculations had been given during the convalescence without clinical manifestations. Five days after the last inoculation, however, the temperature began to go up in a very suspicious manner. An inoculation exactly similar to the previous ones now produced a very sharp reaction with a chill. The next morning, however, the temperature returned to normal and remained there. I believe this case would have relapsed if the beginning re-infection had not been nipped in the bud by the inoculation.

SUMMARY.

The study of specific therapy in 130 cases of typhoid fever has brought out the following facts:

(1) That specific therapy, confined to the original disease, increases, apparently, the tendency of the disease to relapse.

(2) That by therapeutic inoculation, however (Vaughan's nontoxic residue), continued into convalescence, the relapse in typhoid fever can be largely eliminated. This claim is made with much assurance, but is, of course, subject to confirmation by observation upon a much larger series of cases. If relapses can be prevented then it follows almost certainly that mild typhoid infections can be aborted. This study would show, furthermore,

(3) That to get the best results cases must be seen as early as possible in the infection, but

(4) That an early diagnosis in typhoid is oftentimes impossible, and that, for this reason, specific therapy suffers under a severe handicap.

(5) That antityphoid serum was no more effective than filtrates and residues and was infinitely more expensive.

(6) That typhoid filtrates may exert a powerful effect upon the clinical course of the typhoid process, their use being followed in many instances by chills, or rise in temperature and pulse, these being followed in their turn, oftentimes, by marked fall in temperature, pulse and respiration, and a general improvement in the clinical picture. The nature of these reactions is still unknown. It is hoped that further study, especially that of the

opsonic index, in connection with these reactions, may give valuable information concerning their nature.

(7) That the nontoxic residue of the typhoid bacillus as prepared by Professor Vaughan seems to make the typhoid process longer, but milder. As stated above, it is apparently very effective in the prevention of relapses.

MODERN OPERATIONS FOR COMPLETE REMOVAL OF THE PROSTATE.

BY ARTHUR TRACY CABOT, A.M., M.D., BOSTON,
Consulting Surgeon at the Massachusetts General Hospital.

AT the present time two methods of complete prostatectomy are being urged by earnest advocates: one is the suprapubic method and the other the perineal; both of these methods usually permit of thorough removal of the prostate. The choice between them should be based on the relative mortality of the operation, the quickness of recovery, and upon the degree of restoration of function obtained by each.

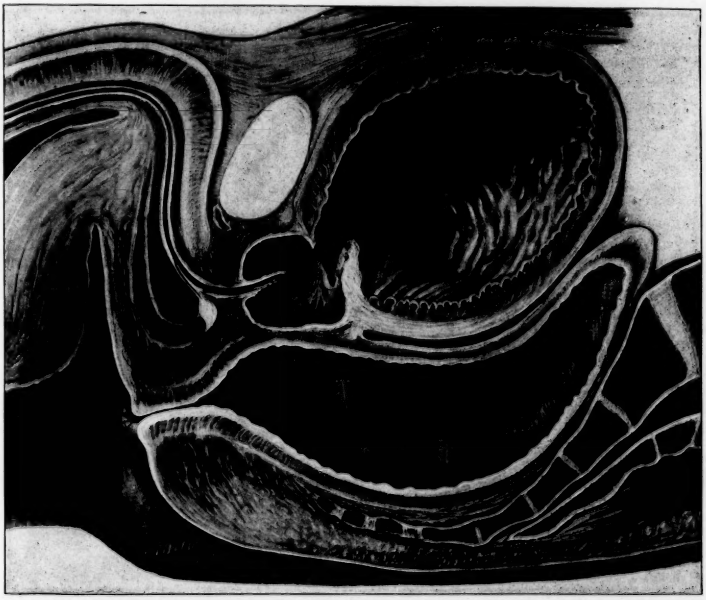
In order to decide these points and make a wise selection between these operations, it is, therefore, important to assemble statistics which shall give us reliable data, both as to mortality and as to after condition. Something is also to be said in regard to the technical difficulties which surround each operation.

I operated first by the suprapubic route, because it was an easy method of approach to the gland, requiring but little dissection. Since, however, I began to use the perineal operation I have gradually used it more and more, and I now find that I regard it as the method of choice, and I apply it to every case in which the removal of the prostate is the prime object of the operation. This change of practice has come about because I have found that although it takes a somewhat longer dissection to reach the prostate by the perineal route, the opportunity for accurate inspection and exact operative procedure is so much better as to wholly outweigh the added difficulties of the dissection. Some operators consider it of no consequence whether the prostatic urethra is torn much or little during the operation. The fact that good results are obtained when all of the urethra within the prostate is torn out with the gland leads many to think that it matters little what happens to the prostatic urethra, anyway. I cannot share this view, for I believe that when the prostatic urethra is for the most part preserved in its proper relations, not only is the healing and restoration of the parts more speedy but the chance of satisfactory restoration of function is more sure. Young has cited facts to show the retention of sexual power when the utricle and seminal ducts are spared. I believe that the restoration of satisfactory urination is more sure when the prostatic urethra has not been seriously torn.

One cause for lack of success in complete prostatectomy has been from the formation of flaps of mucous membrane which have afterwards acted as valves to hinder urination. These flaps form in two places: at the vesical outlet and at the apex of the prostate where it joins the membranous urethra. If the prostate is enucleated from above, the mucous membrane is broken through with the finger at the vesical outlet and through this opening the gland is stripped out. Working from above downwards, it must not infrequently happen that a portion of the urethra towards the apex of the prostate is left, while the portion of the urethra towards the bladder is thoroughly removed. This part of the urethra which is left projects back into the cavity from which the prostate has been shelled out. It forms, as it were, a cuff. It may be readily seen that with the current of urine flowing down from above, this cuff of mucous membrane, by folding from side to side, may readily close the opening of the urethra from an obstructing valve. Operating through the perineum with a wide incision, which allows the parts to be brought into view, the various steps of the operation are under the guidance of the eye, and the difficulties above described are easily avoided. The enucleating finger, entering at the apex of the prostate, separates the gland from its outer capsule, then from the vesical side, and lastly strips it off from the urethra. This separation of the gland from the urethra is done from within outwards, can be assisted by the scissors and blunt dissector and preserves the urethral wall for the most part.

Up to this stage of the operation the only damage done to the urethra has been the opening through which the tractor was introduced, and usually some tearing of its floor. The roof of the urethra is left intact. There is no cuff of mucous membrane which can roll in and form a valve. In a difficult case when the urethral wall is torn more than is usual the rent is so disposed that any flap that is formed is attached about the orifice of the bladder so that the urine as it flows out does not double it up in front of the stream but rather washes it out flat and escapes by it. If now there is a third lobe which has a broad base, it can be readily removed through the cavity left by the removal of the lateral lobes. If a very prominent third lobe is peeled out without removing the mucous membrane covering it a large loose flap is left which may act as a valve and obstruct the vesical orifice just as the third lobe itself did. When there is a pedunculated third lobe I prefer, therefore, to pull it out from the urethra and to cut it off with the thermocautery, removing its mucous membrane with it. In some cases there are several projections into the bladder, all of which can be dealt with in the same manner. By cutting off these pedunculated outgrowths *in toto* we avoid the formation of flaps of mucous membrane, which may afterwards act as valves. The vesical opening left after the removal of the lateral lobes is ample for the handling of a good-sized third lobe. I have found the lithotomy scoop a useful instrument in pulling down these projecting growths and have never been seriously hampered by want of room to properly deal with them.

Three times in the past three years I have encountered small obstructing prostates which could not be enucleated. One of these I approached from above, and finding a bar at the neck of the bladder I cut and cauterized it as deeply as seemed safe with so small a prostate. This operation was followed by but little improvement. The other two cases I treated by perineal prostatectomy. Finding that the glands would not peel out I cut them out piecemeal with rongeur forceps



The histories of these two fatal cases are as follows:

Case 14. E. F. S., aged seventy-seven, entered the hospital March 26, 1905, with a history that he had been for ten years troubled with frequent urination.

Four weeks before entrance he began to feel as if he did not empty the bladder.

Three weeks ago the urine stopped. He then resorted to the catheter, which has been used ever since.

Two days ago he began to have difficulty in using

Diagrammatic drawing, showing above, a flap of mucous membrane left by shelling out a prominent third lobe, and below, a remnant of the urethral mucous membrane extending back into the cavity from which the prostate has been removed — either of which would tend to form a valvular closure of the urethra.

of the comfort of keeping the dressings dry. The in-lying catheter does not interfere with getting the patients out of bed, and it is our practice to get them up as soon as possible, for they seem to do better when moving about.

Mortality. — In the past four years I have operated on thirty-five cases by perineal prostatectomy. Two cases have died; one three days after operation, the other at the end of a month.

After this the quantity of urine fell till, on April 24, it was 50 oz. in twenty-four hours, with a specific gravity of 1,018.

He now became flighty in his mind, pulled out his tube, and had a catheter introduced through the urethra. He was gotten out of bed, thinking that this might improve his condition, but, although the quantity of urine became fairly good, he gradually became more and more feeble and died on May 18, one month after operation.

opsonic index, in connection with these reactions, may give valuable information concerning their nature.

(7) That the nontoxic residue of the typhoid bacillus as prepared by Professor Vaughan seems to make the typhoid process longer, but milder. As stated above, it is apparently very effective in the prevention of relapses.

function is more sure. Young has cited facts to show the retention of sexual power when the utricle and seminal ducts are spared. I believe that the restoration of satisfactory urination is more sure when the prostatic urethra has not been seriously torn.

One cause for lack of success in complete prostatectomy has been from the formation of flaps of mucous membrane which have afterwards acted as valves to hinder urination. These flaps form in two places: at the vesical outlet and at the apex of the prostate where it joins the membranous urethra. If the prostate is enucleated from above, the mucous membrane is broken through with the finger at the vesical outlet and through this opening the gland is stripped out. Working from above downwards, it must not infrequently happen that a portion of the urethra towards the apex of the prostate is left, while the *toto* we avoid the formation of flaps of mucous membrane, which may afterwards act as valves. The vesical opening left after the removal of the lateral lobes is ample for the handling of a good-sized third lobe. I have found the lithotomy scoop a useful instrument in pulling down these projecting growths and have never been seriously hampered by want of room to properly deal with them.

Three times in the past three years I have encountered small obstructing prostates which could not be enucleated. One of these I approached from above, and finding a bar at the neck of the bladder I cut and cauterized it as deeply as seemed safe with so small a prostate. This operation was followed by but little improvement. The other two cases I treated by perineal prostatectomy. Finding that the glands would not peel out I cut them out piecemeal with rongeur forceps and then with a finger as a guide in the bladder I cut away the bar, bit by bit, till nothing was left but soft mucous membrane. In both of these cases the restoration of urination was thoroughly good.

My personal experience then has been that the restoration of function is more complete and lasting after the perineal than after the suprapubic operation. The control of hemorrhage I have found distinctly easier by the perineal route. A strip of gauze can be snugly packed into the prostatic capsule and then the end can be brought down through the outer wound which it should not fill tightly, for too much pressure against the rectal wall may produce sloughing and lead to a fistula. In the suprapubic operation it is difficult to apply packing so that it will stay in place and continue to exert pressure against the bleeding surface without so filling the base of the bladder as to exert injurious pressure on the ureters and to cause great discomfort to the patient. In one case of suprapubic prostatectomy I had great difficulty in controlling the hemorrhage, and lost my patient owing, as I thought, to the interference with the kidneys caused by the tight packing. Convalescence after perineal prostatectomy is much quicker and more comfortable than after the suprapubic operation. The tubes can be removed on the third to the fifth day, and after this the patient soon passes his own water with little or no involuntary leakage. At first the larger part of the water comes through the perineal wound and serves the good purpose of keeping this thoroughly washed out. Occasionally, for a few days, the urine comes away involuntarily through the perineal wound. This soon ceases, however, and usually, by the end of a fortnight, the greater part of the urine is passed *per urethram* with little or no escape through the perineum. It has happened in one or two of my cases that after taking out the tubes the patient has been unable to void the urine. In these cases the catheter is easily introduced through the urethra and drainage kept up for a few days in this manner, at the end of which time the power of voluntary urination has been invariably restored. In some few cases the patients preferred to have the catheter retained till the tenth or twelfth day on account of the comfort of keeping the dressings dry. The in-lying catheter does not interfere with getting the patients out of bed, and it is our practice to get them up as soon as possible, for they seem to do better when moving about.

Mortality. — In the past four years I have operated on thirty-five cases by perineal prostatectomy. Two cases have died; one three days after operation, the other at the end of a month.

The histories of these two fatal cases are as follows:

Case 14. E. F. S., aged seventy-seven, entered the hospital March 26, 1905, with a history that he had been for ten years troubled with frequent urination.

Four weeks before entrance he began to feel as if he did not empty the bladder.

Three weeks ago the urine stopped. He then resorted to the catheter, which has been used ever since.

Two days ago he began to have difficulty in using the catheter and he has now gone fourteen hours without having any urine drawn.

The greatly distended bladder was emptied and constant drainage was instituted.

At the time of entrance the urine was 1,027 specific gravity and showed a trace of sugar. Quantity of urine was only 19 oz. in the first twenty-four hours; the next twenty-four hours it rose to 35 oz.; and six days after entrance it rose in twenty-four hours to 85 oz., falling back, however, to 55 and 42 on the following days.

The patient was troubled with bronchitis of a chronic nature. Operation was put off in the hopes of somewhat improving this condition. However, his condition was so uncomfortable and manifestly getting worse that operation was undertaken on April 11.

In cutting into the prostate, considerable pus escaped and was pressed out during the subsequent enucleation.

The patient made a good recovery from ether, but on the following day the temperature rose to 101° and at night reached 103°. The quantity of urine in that twenty-four hours was 20 oz. and the specific gravity 1,018.

On the 13th of April, the temperature remaining up, the patient showed cyanosis, and râles were found at the base. The quantity of urine in this twenty-four hours rose to 40 oz. and contained 1.3% sugar.

On the 14th the patient became unconscious. The quantity of urine rose to 90 oz., with 3% sugar, and having a specific gravity of 1,028.

The patient died in the afternoon, and unfortunately an autopsy could not be obtained.

Case 15. P. P., aged sixty-one, entered the hospital April 10, 1905.

At time of entrance the patient was stupid and urine was tinged with blood. Patient said that he had always urinated well till five weeks ago, when he was seized with acute retention and catheterized. Since that time he has dribbled his urine in small quantities, with an occasional catheterization.

At the time of entrance the bladder extended above the umbilicus and the catheter introduced drew 40 oz. without emptying the bladder. Three hours later 20 oz. were drawn and in the evening of that day he was placed on constant drainage.

Two days after entrance the quantity of urine was 100 oz. in the twenty-four hours, specific gravity being 1,010.

On April 20 perineal prostatectomy was done, following which he passed 100 oz. of urine, with a specific gravity of 1,017.

After this the quantity of urine fell till, on April 24, it was 50 oz. in twenty-four hours, with a specific gravity of 1,018.

He now became flighty in his mind, pulled out his tube, and had a catheter introduced through the urethra. He was gotten out of bed, thinking that this might improve his condition, but, although the quantity of urine became fairly good, he gradually became more and more feeble and died on May 18, one month after operation.

No.	Age.	Name.	Residence.	Duration.	Amt. of Obstruction.
1	64	E.	Medford, Mass. Hospital case.	3 years.	Catheterized himself every 4 hours.
2	73	C.	Everett, Mass. Hospital case.	3 weeks.	Depends entirely on catheter since first attack.
3	56	S.	Amesbury, Mass. Hospital case.	7 years.	Depends on catheter entirely. Litholapaxy 3 days before operation.
4	54	N.	Dover, Mass. Hospital case.	7 years.	For 2 years urine dribbled. Bladder distended to umbilicus.
5	65	M.	Boston, Mass. Private case.	1 year.	Residual, 8 oz. in 1903. Later depended wholly on catheter.
6	68	C.	Haverhill, Mass. Hospital case.	2 years.	2 years ago frequency every 3 hours, now every 10 or 15 minutes.
7	71	H.	Milford, N. H. Private case.	3 years.	Frequency 21 times in 24 hours. Bladder distended above umbilicus.
8	72	L.	Cambridge, Mass. Hospital case.	Few weeks.	April 23 abdomen distended to umbilicus; 83 oz. drawn by catheter. Constant drainage.
9	53	V.	Cambridge, Mass. Hospital case.	11 years.	For 6 months used catheter once a day. Residual, 15½ oz.
10	71	R.	Haverhill, Mass. Hospital case.	12 years.	Urinates every hour or less in day, 1 to 3 hours at night.
11	57	F.	Haverhill, Mass. Hospital case.	2 months.	11 days ago stoppage. Since, catheter twice a day.
12	65	G.	Hospital case.	8 years.	Glycosuric. Past month dependent on catheter. Ten days ago could not introduce catheter. Constant drainage.
13	60	G.	East Dedham, Mass. Hospital case.	10 years.	Occasion use of catheter for retention. Entirely last two months.
14	77	S.	Hyannisport, Mass. Hospital case.	10 years.	Dependent on catheter for past 3 weeks.
15	61	P.	Roxbury, Mass. Hospital case.	5 weeks.	5 weeks ago acute retention. Catheter several times since. Abdomen much distended.
16	64	C.	Cambridgeport, Mass. Hospital case.	5–6 years.	Uses catheter 3 times daily.
17	78	H.	Haverhill, Mass. Hospital case.	10 years.	Suprapubic operation in 1897. Has used catheter for two years.
18	64	C.	Boston, Mass. Private case.	16 years.	Occasional use of catheter. Residual, 1⅛ oz.
19	62	P.	Hudson, N. H. Private case.	15 years.	For year used catheter 1–3 times at night, once in day.
20	69	M.	Rockland, Mass. Private case.	10 years.	Residual, 3 oz.
21	61	C.	Harwich, Mass. Hospital case.	7–8 years.	Acute retention 2 days ago. Bladder distended from umbilicus to pubes.
22		S.	Boston, Mass. Private case.	Many years.	Stream always sluggish. Recently almost stopped: after recovery, residual, 8 oz.
23	66	A.	Dorchester, Mass. Private case.	6 years.	Residual, 3½ oz. Urinates once an hour in day, only twice at night
24	60	S.	Cambridge, Mass. Hospital case.	1 year.	April 13 stoppage; 50 oz. by catheter. Catheter most of time since. Residual, 8 oz.
25		F.	Peabody, Mass. Private case.	2 years.	Increasing frequency and difficulty in urination. Worse past 6 weeks, requiring catheter.
26	64	W.	Waltham, Mass. Private case.	3 years.	Residual, 3 oz. Frequency, every hour or two during day.

DATE OF OP.	RESULT.	PATHOLOGY.	CONDITION AFTER RECOVERY.
Feb., 1904.	Recovered.	Glandular hypertrophy.	Six months later urinates every 3–4 hours. "Feels a new man." No residual. March, 1905, same report.
Feb., 1904.	Recovered.	Glandular hypertrophy.	March, 1905, all urine per urethra. Residual, 2 dr.
Feb., 1904.	Recovered.	Hypertrophy of glands.	March, 1905, no residual. Better than for 20 years. Perfect control.
March, 1904.	Recovered.	Glandular hypertrophy.	One month later no residual.
March, 1904.	Recovered.	Diffuse hypertrophy. Small prostate.	In 1907, good health. Passes all urine naturally. Residual in 1906, 2 dr.
April, 1904.	Recovered.	Glandular hypertrophy.	May, 1905, very well since operation.
May, 1904.	Recovered.	Glandular hypertrophy with cystic dilatation.	Four months later residual 2–2½ oz.
May, 1904.	Recovered.	Glandular and cystic hyperplasia.	Urination restored. At first residual. 17 oz.; one month later fell to 5 oz. At that time used catheter once a day.
May, 1904.	Recovered.	Simple hypertrophy.	One month later passing urine with very little pain. Residual, 4–6 oz.
May, 1904.	Recovered.	Glandular hypertrophy.	Last of July better than for years. No residual. June, 1905, much improved. Perfect control.
June, 1904.	Recovered.	Glandular hypertrophy.	Seen in September. Very well. Urination normal. June, 1905, symptoms all relieved.
Feb., 1905.	Recovered.	Chronic glandular hypertrophy.	April, 1906, well since operation. Urinates every 4 hours, once at night. Residual, 2½ oz. Sugar intermittent, now quite 1%.
Feb., 1905.	Recovered.	Glandular hypertrophy.	Calculi removed. March, 1906. No difficulty. "Never felt better." M. G. H.
April, 1905.	Died.	Glandular hypertrophy.	Sugar found in small amount. Passes 90 oz. urine. No autopsy. M. G. H.
April, 1905.	Died.	Glandular hypertrophy.	Died one month later of pneumonia. M. G. H.
June, 1905.	Recovered.	Adenoma.	Jan., 1907, died of heart failure. "Had no trouble with urination since operation." M. G. H.
Oct., 1905.	Recovered.	Cystic adenoma.	M. G. H.
Nov., 1905.	Recovered.	Glandular hypertrophy with retention cysts.	Jan., 1906, felt well. Urinates every 1½–2½ hours. Residual, ½ oz.
Dec., 1905.	Recovered.	Adenoma.	July 30, 1905, ½ oz. "Feels 100% better since operation."
Jan., 1906.	Recovered.	Adeno-fibroma with cystic formation.	No residual.
April, 1906.	Recovered.	Cystic adenoma.	One month after operation residual, ½ oz.
April, 1906.	Recovered.	Glandular hypertrophy.	Urination normal. No residual.
April, 1906.	Recovered.	Glandular hypertrophy.	June 23. No residual.
May, 1906.	Recovered.		
June, 1906.	Recovered.	Glandular hypertrophy.	June, 1907. Urinates 4 times in day, once at night. "Feels like a boy."
Nov., 1906.	Recovered.	Cysto-adenoma.	No residual. Reported in June, feeling very well, with no discomfort whatever about urination.

No.	Age.	Name.	Residence.	Duration.	Amt. of Obstruction.
27		P.	Brighton, Mass. Private case.	3 years.	Residual, 2 oz. Urinates with difficulty every 2 hours. Several attacks of inflammation with great discomfort.
28	70	L.	Brighton, Mass. Private case.		For 20 years slowness of stream. Of late worse, and required catheter twice a day. Residual, 30 oz.
29	75	O.	Neponset, Mass. Private case.	4 years.	Wears a catheter all the time.
30		W.	Peabody, Mass. Private case.		One year plus; frequency every hour. Residual, 15 oz.
31		F.	Westboro, Mass. Private case.	5 years.	Residual, 2–4 oz. Used catheter occasionally.
32	72	H.	Maine. Private case.	15 years.	For past 2 years used catheter chiefly. Residual, 12 oz.
33	65	W.	Wellesley Farms, Mass. Private case.	10 years.	Suprapubic in 1899. Difficulty returned until dependent on catheter, using 8 times in 24 hours.
34	65	C.	Brookline, Mass. Private case.	6 years.	Bladder difficulty, catarrh, etc. Catheter twice a day.
35		W.	Tyngsboro, Mass. Private case.	About 2 years.	Increasing difficulty and occasional retention, requiring catheter.
36		F.	Worcester, Mass. Private case.	4 years.	Gradually increasing slowness of stream. Never pain or frequency. Lately catheter twice a day. Residual, 25 oz.

The symptoms in this case were somewhat difficult to understand, and a neurologist who saw him in consultation thought that his condition indicated a previous apoplectic seizure, which had left some mental deterioration.

Case 14. The first of these patients with chronic bronchitis and glycosuria well illustrates the condition of broken health in which many of these patients come to the surgeon.

Case 15 did not die as an immediate effect of the operation but from some toxemia, as I thought, originally, due to the obstruction in the prostate with its secondary effects on the kidneys. In both cases, however, the operation failed to keep them alive and they should be rated in the mortality risk.

They give a death-rate of 5.5% in this small series of cases. This is somewhat higher than the mortality rate in the statistics of some operators, and higher, I believe, than the normal risk of the operation. I have now had 21 successive recoveries due in part, doubtless, to increased skill in operation and to experience in after-treatment.

Young reports 60 successive cases without a death. In no one of the 33 cases that recovered was there a failure to restore the power of voluntary urination, and in no case was there incontinence. In one case (case 8) the bladder was distended by 83 oz. of urine when he came under treatment. At first, after operation, the residual urine was 17 oz., it had fallen to 5 oz. one month later. He was then lost sight of. He had been freed from the constant thraldom of the catheter, but found its occasional use of advantage in keeping the bladder clean. Case 9 had a residuum of 15½ oz. before operation, and one month after operation was passing urine with a little discomfort and had a residual urine of from 4 to 6 oz.; he was then lost sight of. It is to be remembered that in many cases of prostatectomy the full measure of improvement is not reached for several months.

From these cases and from others I have received the impression that a certain proportion of these patients, whose bladders have been long distended, lose the expulsive force to such a degree that they are afterwards unable to completely void the urine even when the obstruction is wholly removed. This is due not only to the induced atony of the walls but also to the saeculation which forces portions of the mucous membrane out between the muscular bundles so that the sacculi have no contractile tissue in their walls and so are unable to empty themselves when the bladder closes down.

It remains to speak of my experience with rectal injury, which is constantly urged as an opprobrium of the perineal operation. In case 5 the vigorous traction of a retractor tore a rent about an inch long, transversely, across the rectal wall. It was closed with a double row of chromic gut stitches and healed by first intention without causing any trouble. Since that experience I have always covered the rectum with the end of a gauze sponge and have found this a perfect protection. In case 17, an old and broken man of seventy-eight, who had had a partial prostatectomy by the suprapubic route eight years before,

Date of Op.	Result.	Pathology.	Condition after Recovery.
Nov., 1906.	Recovered.	Glandular hyperplasia with retention cysts.	Seen in June, 1907. Was perfectly well. Passing water normally. Regarded himself as greatly benefited by operation.
Nov., 1906.	Recovered.	Glandular hyperplasia with retention cysts.	In excellent health. Free and comfortable urination, 5 or 6 times in 24 hours.
Dec., 1906.	Recovered.	Glandular hypertrophy.	June, 1907. Urination easy and comfortable, 5 times in day, 3 at night. Has gained weight; in good health.
Jan., 1907.	Recovered.	Glandular hyperplasia with cystic dilatation.	In good health.
Jan., 1907.	Recovered.	Glandular hyperplasia.	
Feb., 1907.	Recovered.	Glandular hypertrophy.	April. Holds urine 6 hours. Feels better than for years.
March, 1907.	Recovered.	Glandular and fibrous hypertrophy.	April. Residual, 3½ oz. Urination every 2 hours in day, twice at night.
March, 1907.	Recovered.	Glandular and fibrous hypertrophy.	April. Residual, 3 oz.
March, 1907.	Recovered.	Glandular hypertrophy.	June, 1907. No difficulty in urination. No frequency in day, once in night.
June, 1907.	Recovered.	Glandular hypertrophy.	

was greatly troubled by a persistent suprapubic fistula. For six years he passed water unsatisfactorily by the natural efforts, but for two years he had returned to the use of the catheter. In the hope of relief from his fistula he decided upon further operation. The effect of the former operation seemed to have been to fix the prostate rather high in the pelvis so that it was more than usually difficult to reach from the perineum. The hemorrhage was no more than it often is, but the already feeble condition of the patient caused apprehension on this score, and after he was in bed an extra gauze was packed into the outer wound. The pressure of this led to a slough in the rectal wall which caused a fistula that was slow to heal and greatly prolonged the convalescence. Voluntary urination was re-established and the suprapubic fistula closed, but there continued to be a considerable leakage into the rectum. In both of these cases the injury to the rectum was due to lack of experience on my part and in both cases the difficulty was preventable.

Preparatory treatment. — It often happens that these patients reach the surgeon in a condition very unfavorable for operation. The two fatal cases illustrate this. Other cases which seemed equally unfavorable were so improved by preparatory treatment as to bear the operation perfectly. Case 25 was an example of a severe cystitis with probably pyelonephritis and certainly uremia, who required one month of preparation before operation could be safely undertaken.

Case 25. Mr. F., sixty-three years of age. Seen by me May 11, 1906. For two years he had had increasing frequency and difficulty in urination. Six weeks before I saw him the difficulty of urination had greatly increased and required the constant use of a catheter. For several days he had had fever and nausea. He was of feeble muscular development though he had had but little illness during his life. Examination showed him to be mentally confused, with a feeble, irregular pulse, a dry, brown tongue, anorexia and persistent nausea. The bladder could be felt moderately distended and the prostate was smoothly and evenly enlarged. The catheter passed easily and drew about a pint of very cloudy urine and at the end about 2 oz. of pus flowed out. The catheter was fastened in for constant drainage. Liquid diet with as much water as he could comfortably take. First twenty-four hours, 60 oz. of urine, much clearer than had been drawn at entrance. Specific gravity 1,008, albumin trace, urea 19 gm. The urine quickly increased in amount up to 120 oz., and his power of taking food improved, but slight occasional nausea with a dry tongue persisted for a long time. Finally, at the end of a month, during most of which time the amount of urine had remained above 100 oz., the tongue cleared off, the pulse became steady at about 70 and perineal prostatectomy was done.

Pathological report: Glandular hypertrophy with retention cysts.

Convalescence was slow but steady. This patient was up in five days but the wound healed very slowly. Reported in November: "Passes water four times in day, once in ngiht." "Feels like a boy." Case 12 was an instance of glycosuria which was so improved by treatment that a prostatectomy was well borne.

The accompanying table gives the essential details of this series of cases.

THE REACTION OF SOME MILK MODIFICATIONS TO RENNET.

BY H. ILLOWAY, M.D., NEW YORK.

IN the course of the examination of the gastric chemical processes, the examination for pepsin or pepsinogen and for rennet or labzymogen has become with me part of the regular routine.

The method employed for rennet is that of Leo, namely, the addition of a few drops of gastric filtrate to a certain quantity of milk.

On one occasion, on a Sunday, being anxious to complete the examination for a patient who was about to depart, and not having any liquid milk at hand, and being unable to obtain any (the stores being already closed), I took some fresh condensed milk (unsweetened)[1] which was in the house, and making a solution of what I deemed the proper strength, made use of that. Apparently no reaction followed. The fluid remained fluid, even after standing in the thermostat at a temperature of 40° C. a much longer time than is ordinarily required with fluid milk.[2]

No result having been obtained, I was uncertain whether this was because of the character of the milk or because the gastric filtrate had spoiled. However, a retrial of the latter the next morning demonstrated that it was in good condition and the rennet therein very active, a proper rennet cake (Labkuchen) being promptly formed.

The fault lay therefore in the milk.

I repeated the experiment with the solution of condensed milk several times, but always with the same result, — no reaction apparently, the fluid remaining (as shown by a jarring of the thermostat) fluid.

Without any further inquiry into the matter I concluded that for some reason, to me then unknown, this form of milk was not adapted to this special purpose, to wit, testing for rennet, and I did not use it so again.

Last year, 1906, a rather striking incident occurred in the course of practice that recalled my former experiences with condensed milk, and thereupon I concluded to make a careful investigation of the action of rennet upon this form of milk modification.

The method employed was that of Leo, but with the extensions thereof made by myself, as described in the article already referred to.[3]

The gastric filtrates used in these investigations were all tried by preceding control tests, and only those found normally active[4] were employed.

A. CONDENSED MILK (unsweetened).

The first three examinations are of a series made at longer intervals and not *seriatim* as regards the quantity of gastric filtrate used.

No. I. One Teaspoonful of Condensed Milk to 4 Oz. of Water.

(*a*) 20 cc. of milk + 1 cc. of gastric filtrate.
(*b*) 20 cc. of milk + 5 cc. of gastric filtrate.

Result:

(*b*) In eight minutes coagulation of the casein in very fine, minute flocculi. On removing the glass from the thermostat and letting the mixture stand a little while longer, the flocculi sink to the bottom, forming a rather granular looking layer, and the serum floats on top. Shaken, they mix again and well with the serum.

(*a*) In twenty minutes there was coagulation of the casein in fine, minute flocculi, but not separated from the serum. After standing for some time, the flocculi began to settle at the bottom, but on the whole the separation was not so complete as in *b*.

No. II. One Teaspoonful of Condensed Milk to 6 Teaspoonfuls of Water.

(*a*) 10 cc. of milk + 5 drops of gastric filtrate.
(*b*) 20 cc. of milk + 5 drops of gastric filtrate.

Result: The process was slow.[5]

(*a*) In about forty minutes.
(*b*) In seventy-five minutes.

The reaction was the same as obtained in No. I, to wit, a coagulation of the casein in very fine, minute flocculi which remained in the serum, and only after quite a time tended to settle at the bottom.

No. III. Same Solution.

(*a*) 10 cc. of milk + ½ cc. of gastric filtrate.
(*b*) 20 cc. of milk + 1 cc. of gastric filtrate.

Result: In thirty minutes the reaction occurred in both, coagulation of the casein in very fine, minute flocculi. Allowed to remain in the thermostat for a further half hour, the mixture showed no change.

The following three tests, a retrial to verify the results obtained in the first series, were made at brief intervals and *seriatim* as to the quantity of gastric filtrate used.

No. IV. Same Solution.

(*a*) 10 cc. of milk + 5 drops of gastric filtrate.
(*b*) 20 cc. of milk + 5 drops of gastric filtrate.

Result:

(*a*) In forty-five minutes coagulation of the casein in very fine, minute flocculi.

(*b*) In one hour, the same result.

After standing some time the mixture separated into layers, floccular at the bottom, serum on the top.

No. V. Same Solution.

(*a*) 10 cc. of milk + 1 cc. of gastric filtrate.
(*b*) 20 cc. of milk + 1 cc. of gastric filtrate.

Result: In forty-five minutes, in both, coagulation of the casein in very fine, minute flocculi, as in No. IV.

No. VI. Same Solution.

20 cc. of milk + 5 cc. of gastric filtrate.

Result: In twenty-five minutes a coagulation of the casein in fine, minute flocculi, as in all the preceding tests.

The results of these various tests demonstrate that in this form of milk the addition thereto of

[1] Such as is delivered every morning in small glass jars.
[2] Archiv. für Verdauungskrankh., Bd. 11. Illoway: "Einfache Methoden zur quantitativen Bestimmung der vom Magen ausgeschiedenen Enzyme."
[3] *Loc. cit.*
[4] *Loc. cit.*
[5] *Ibid.*

rennet produces the same form of casein coagulation as obtains in the human mother's milk.

This was the reason why I failed to obtain the characteristic reaction resulting in ordinary milk to which I had become accustomed.

The question now arose, Would the *sweetened* condensed milk react in the same way?

B. CONDENSED MILK (sweetened, in tin cans).[6]

No. I. One Teaspoonful of Milk to 6 Teaspoonfuls of Water.

(*a*) 10 cc. of milk + 5 drops of gastric filtrate.
(*b*) 20 cc. of milk + 5 drops of gastric filtrate.
Result: The process was slow.
(*a*) In one hour coagulation of the casein in fine flocculi,
(*b*) In about one hour and three quarters.
The flocculi, though very small, were, nevertheless, somewhat larger than those resulting in the unsweetened milk.

After being placed in the thermostat, the whole became a little thicker (more syrupy) than the unsweetened milk.

No. II. Same Solution.

(*a*) 10 cc. of milk + ½ cc. of gastric filtrate.
(*b*) 20 cc. of milk + 1 cc. of gastric filtrate.
Result: Same as in No. III, Series A, the only difference being that the flocculi resulting were slightly larger, as already recorded with No. I of this series.

Repetition of tests for verification.

No. III. Same Solution.

(*a*) 10 cc. of milk + 5 drops of gastric filtrate.
(*b*) 20 cc. of milk + 5 drops of gastric filtrate.
Result:
(*a*) In forty-five minutes coagulation in fine flocculi.
(*b*) In one hour coagulation in fine flocculi, the flocculi slightly larger than those obtained in No. IV, Series A.

No. IV. Same Solution.

(*a*) 10 cc. of milk + 1 cc. of gastric filtrate.
(*b*) 20 cc. of milk + 1 cc. of gastric filtrate.
Result: In thirty-five minutes coagulation of the casein in fine flocculi, as already described.

No. V. Same Solution.

20 cc. of milk + 5 cc. of gastric filtrate.
Result: In fifteen minutes coagulation of the casein in fine flocculi.

From the foregoing it is evident that the same result was obtained with the sweetened as with the unsweetened condensed milk, namely, an even coagulation of the casein in fine, very small flocculi which do not precipitate from the serum very readily, but are held intermixed with it for a comparatively long time.

The only difference between these two forms of condensed milk, so far as we are here concerned, is this, that the flocculi are slightly larger in the sweetened than in the unsweetened milk.

[6] Eagle brand was used.

Having gone thus far, it interested me to know how some other milk modifications would be affected, and a series of similar tests was undertaken with these.

C. MODIFIED MILK (commercial).

No. I. Modified Milk for an Infant Two Months Old.[7]

(*a*) 10cc. of milk + 5 drops of gastric filtrate.
(*b*) 20 cc. of milk + 5 drops of gastric filtrate.
Result: In both, coagulation in fine flocculi, like those described as occurring in Series B.

No. II. Modified Milk, 4.6.1.50.

(*a*) 10 cc. of milk + 5 drops of gastric filtrate.
(*b*) 20 cc. of milk + 5 drops of gastric filtrate.
Result:
(*a*) In fifteen minutes.
(*b*) In twenty-five minutes.
A regular rennet cake (Labkuchen) formed, though not of such firm texture as in ordinary milk.

No. III. Modified Milk, 4.7.2.

(*a*) 10 cc. of milk + 5 drops of gastric filtrate.
(*b*) 20 cc. of milk + 5 drops of gastric filtrate.
Result:
(*a*) In ten minutes.
(*b*) In twenty-five minutes; rennet cake as described in No. II above.
(*a*) 10 cc. of milk + 5 drops of gastric filtrate.
(*b*) 20 cc. of milk + 5 drops of gastric filtrate.
Result:
(*a*) In twelve minutes.
(*b*) In twenty-five minutes; rennet cake as described.

The reason for the repetition: In the first test a mixed gastric filtrate was used, in the second test a single gastric filtrate. In both No. II and No. III the rennet cake (Labkuchen) had not the smooth, solid texture seen in that formed in ordinary milk, but presented a more loose, a *meshed* appearance.

No. IV. Modified Milk, 4.7.2.

(*a*) 10 cc. of milk + 1 cc. of gastric filtrate.
(*b*) 20 cc. of milk + 1 cc. of gastric filtrate.
Result:
(*a*) In twenty-two minutes thickened; in thirty minutes rennet cake.
(*b*) In thirty minutes thickened; in forty-five minutes rennet cake well formed; in one hour serum separating in both.

No. V. Modified Milk, 4.7.2.

20 cc. of milk + 1 cc. of gastric filtrate.
Result: In twenty minutes the rennet cake was seen at the bottom of the glass and the serum that had separated, above it. In twenty-five minutes rennet cake of fair firmness.

No. VI. Modified Milk, 4.7.2.

20 cc. of milk + 5 cc. of gastric filtrate.
Result: Coagulation of casein set in almost immediately. The mixture being put into the ther-

[7] I had asked for modified milk for this age, and the tag attached to the bottle bore this inscription.

mostat, at the end of ten minutes rennet cake seemed formed and serum separating from it.

The rennet cake was of very loose texture, more an aggregation of large flocculi, and segments could be separated easily by a light shaking of the glass.

No. VII. Modified Milk, 3.6.2.

(*a*) 20 cc. of milk + ½ cc. of gastric filtrate.
Result: After forty minutes coagulation in large flocculi floating loose in serum.
(*b*) 20 cc. of milk + 1 cc. of gastric filtrate.
Result: In thirty minutes rennet cake formed, but of loose texture, *meshed*, as it were.

D. HOME-MADE MILK MIXTURES.

Fluid milk (from a trustworthy source) ℥ij; lime water, ℥ ss; distilled water, ℥ ss.

No. I.

(*a*) 10 cc. of milk + 1 cc. of gastric filtrate.
(*b*) 20 cc. of milk + 1 cc. of gastric filtrate.
Result:
(*a*) In fifteen minutes rennet cake; not so firm as in undiluted milk; breaks up rather easily.
(*b*) In fifty minutes small masses of coagula seen floating around in the serum.

No. II. Same Mixture.

20 cc. of milk + 5 cc. of gastric filtrate.
Result: In twenty-five minutes a loose looking rennet cake, as if made up of separate masses of coagula; much looser than in undiluted milk, or better, a *meshed* rennet cake.

No. I. Milk, ℥ ij; Distilled Water, ℥ j.

(*a*) 10 cc. of milk + 5 drops of gastric filtrate.
(*b*) 20 cc. of milk + 5 drops of gastric filtrate.
Result:
(*a*) In fifteen minutes coagulation; removed from thermostat and allowed to stand for one-half hour; serum beginning to separate, rennet cake firm as in undiluted milk.
(*b*) In forty-five minutes rennet cake, as described above.

No. II. Same Mixture.

(*a*) 10 cc. of milk + 1 cc. of gastric filtrate.
(*b*) 20 cc. of milk + 1 cc. of gastric filtrate.
Result:
(*a*) In eight minutes, coagulation, rennet cake.
(*b*) In twenty-five minutes; in twenty minutes, serum separating.

No. III. Same Solution.

20 cc. of milk + 5 cc. of gastric filtrate.
Result: At the end of fifty-five minutes well-formed rennet cake and serum separated from it, firmer in texture than that resulting in the milk mixture containing lime water, and almost as firm in texture (in appearance) as that produced in undiluted milk.

As to any slight discrepancies in the time of reaction, these must be laid to the account, *firstly*, of the variation in the amount of the casein contained in the different modifications and solutions, and, *secondly*, to that of different gastric filtrates. As I have shown in the article on the quantitative determination of the gastric enzymes, already referred to, the *normal time limit* in which the *normal* reaction is produced in the ordinary liquid milk by gastric filtrates derived from different individuals is not a hard and fixed one, but has a certain range, as there set forth.

The reason for making tests with three different quantities of gastric filtrates was this: the first, the smallest, quantity, to show the character of the reaction, and the two others, the larger quantities, to show how it would be in the stomach, where much larger quantities of the enzyme come in contact with the milk.

It was for this reason mainly, namely, to make the condition as nearly as possible to what it would be in the stomach, that I refrained from neutralizing the larger quantities of gastric filtrate, as is advised by some authors. Moreover, as I have already shown in the article referred to and as can be seen from the tests in the *group D, milk diluted one third with distilled water*, such neutralization is not necessary in so far as the proportions here and there employed are concerned.

THE QUESTION OF "JUSTIFIABLE HOMICIDE."

BY CHARLES GREENE CUMSTON, M.D., BOSTON.

(Continued from No. 13, p. 432.)

IT is to be noted that in these double suicides, often one of the two lovers has motives for killing himself, but jaded by jealousy he persuades the other to imitate him. If life no longer has charms for one of the two, the other without treason will not be able to find it later. Then to this posthumous jealousy becomes joined the egotistical desire for the beloved one to share misfortunes as well as the joys. Here love is not only egotistical, but is also a sacrifice, and the other lover will willingly make the greatest gift that he could offer, that of his life, in order to prove his passion. A young woman of a very quiet character learned that the parents of her lover refused consent to their marriage. When she saw him next time she pointed out to him the great grief of living apart, and then covering him with a thousand caresses she begged him to kill himself as she was to do, saying, "I have decided to die rather than to leave you; give me this proof of love." A large open fire was burning in which they both expired in each other's arms.

In other cases it is the man who, forced to suicide by debts or by some dishonorable action, persuades his mistress to imitate him before killing himself. In one case one of them wrote: "Resolved to finish with life, the wild idea of not dying alone comes to me." The man alone had the motive for killing himself; he persuaded his mistress to imitate him from the fear that after his death she would belong to another. This is a crime by suggestion.

If one believes the explanation upheld by the defense in the case of the double suicide of Chambige and his mistress, it was caused by the desire that the former had not to outlive his dishonesty.

According to this version, which is probably the true one, it was Mrs. N. who had the idea of suicide and imposed it upon Chambige as a condition of their love. We will briefly relate this affair to which we will frequently make allusion.

In the vicinity of Constantine, in a quiet village belonging to an honorable family, pistol shots were heard on a certain day. Upon this the doors were broken open and a young woman was found lying on her bed dead, undressed, her head showing a pistol wound. Beside her lay a young man slightly wounded in the head. The woman belonged to an excellent family, mother of several children, possessing not only a good reputation, but even one of austerity. The man was a young student by the name of Chambige with a restless mind, rendered so by bad literature and friends. Three explanations were at least given for this crime. Chambige gave the following one: Mrs. N. would not outlive her mistake, and imposed as the price of her fall the double suicide. According to one of the explanations proposed by the prosecuting attorney, there was simply rape committed followed by murder; Chambige got his victim into a trap and, after having abused her, killed her. According to still another explanation, Chambige was depraved and mentally low; he was a kind of sadist who wished to procure for himself the sensations of an assassin, according to a statement made by him and which weighed heavily on the minds of the jury.

Occasionally the only motive for a double suicide is jealousy on the part of one of the lovers. Thus the lover of a young married woman, tortured by jealousy that he had for her husband, resolved to kill his mistress and himself. In order to accomplish his end, he described his sufferings to her in such a way that she consented to die with him. She even signed a letter in which they both announced their intention of committing suicide, after which they went out to find the necessary weapon. But, when once in the street, the young woman, regaining her possession, changed her mind and rushed into her house in order to escape her lover. He pursued her, and finding the door locked he climbed in and running up the stairs, rejoined his mistress and shot her, after which he killed himself. One may successively follow all the transitions existing between double suicide and murder. In the last case mentioned, it was not one of double suicide but murder, and another celebrated example will show a still greater separation from voluntary double suicide. In 1889 G. S. fired two shots at his mistress B. G. and then tried to kill himself. The girl died, the assassin lived. It was shown at the trial that for a long time he had endeavored to persuade the girl to kill herself with him, but all in vain. Then, rather than killing himself he did not take into account her refusal and killed her. In this case, S. had tried in the first place to obtain the consent of his victim, but other murderers have not even tried to obtain this consent. Decided to commit suicide they begin by killing the one they love. In a house near Naples there lived a young man, H. A., nineteen years of age, and a young woman with her father. The two young people loved each other, but the father of the girl declared that marriage was impossible. In despair H. A. resolved to kill himself, but before putting an end to his days, he killed the girl. He then fled, took a large dose of arsenic and threw himself out of the window. He died a few days later.

It may happen that the man, after killing the one of whom he is jealous, renounces the idea of killing himself and thus we come back to murder from jealousy, of which we have already spoken.

In a very interesting book by Sighele entitled "Le Crime à Deux," this progression from suicide to crime is made very clear by an excellent table. In consulting this table double suicide wished for and desired by both parties comes first; then after, and already approaching murder, comes suicide, where one of the parties alone has motives for killing himself, the execution of the crime being generally performed by him, in other words, a murderer by persuasion. Then the despairing one begs his companion to commit suicide, but being refused he kills her. In the next class no demand is made, but the crime is committed, and lastly the act is committed from jealousy, but the perpetrator does not kill himself, in which case we have murder, properly speaking.

Jealousy is not the only cause of suicide from love and the motive is often difficult to discover. It is the attraction that death produces over lovers, a kind of "moral vertigo" which seizes them and causes them to express the egotistical desire to die together. The human heart is an unexplored region, and as yet it is impossible to say whether it belongs to the alienist or the psychologist. This need of destruction, in order to better love, seems to have taken possession of the minds of the greatest geniuses; Goethe, Byron, Musset, Vigny, Beaudelaire, were tortured by this thought, and beside poets, no lesser men than Balzac and Renan were also afflicted. These authors have frequently been reproached for expressing these ideas, but in reality one should be more astonished that they had them than otherwise. It is a peculiar disease of the imagination when the thing that man hates the most, namely, death, becomes the object of his desire.

What is the cause of this incomprehensible union of love and death? It is that little by little passion corrodes and finally, when it has invaded everything, it has destroyed all. These unfortunates have no longer anything outside of their love, and this love itself is frequently made a hell of by them; they can no longer live without it, nor with it. They finally renounce life, hoping to find in death an eternal marriage.

Jealousy is not the only sentiment which arms two lovers against each other, and it is often for other reasons that the effects of love more closely resemble those of hatred than those of friendship. In the first place there is the desire of avenging one's honor, the withered honor of a deceived husband, the lost honor of the young girl seduced and abandoned. It is to be understood that this desire of avenging one's honor

does not exclude jealousy, and it is nearly always jealousy of those who have betrayed them, as in the case of the deceived husband or the abandoned girl. But the determining motive which pushes them to crime, that they openly confess to and which is usually true, is the obsession of avenging their honor.

The story of the seduced girl is common and nearly always the same. Generally one is dealing with a coquettish girl, her parents having given her tastes which are disproportionate to her condition, she is more refined than the men of her social class, and she dreams of better things. On the other hand, since her infancy, she has been spoken to of love; it has been laid before her in prose, verse and music, and it finally appears to her that it is the only end in life. Friends, sisters, the parents themselves sometimes, after these dreams, have permitted her to understand the realities. Finally, a man appears upon the scene; he is loved beforehand, he speaks, presses his suit and demands; the fall is soon consummated. He comes to the girl with the egotism of man and his experience. For him love is mere play, and since he is a past master in it he soon comes out conqueror, sometimes astonished by the great ease of his victory and the inexperience of his weak adversary. The illusion, however, is of short duration.

The man promises marriage to his mistress, and for that matter he has promised her most everything else. Then pregnancy occurs. The mistake is forever public, and not only the lover no longer wishes to marry his mistress, but he immediately disappears in order to escape the duties of paternity. What is still worse, it is often to marry another that this man goes away, a cruel injury because it is merited, for the simple reason that the mistress has remained a true woman. The abandonment sums up all the sufferings of the woman, of the mistress and the mother; disdain of her beauty, dishonor, public humiliation, rendered still more painful by the joy of her rival, the loss of the loved one, and, lastly, the fear of approaching misery with a child in her arms. Such are the reasons which have forced seduced girls to avenge themselves, and juries acquit them. Examples are unfortunately far too numerous. "When I heard of the marriage of my lover to another young girl," said a young woman who was being tried for murder, "my exasperation was so great that I formed a project to kill him. I loaded my pistol, disguised myself as a man, and hid myself at a spot where I knew he had to pass. As soon as he came I discharged my pistol at him."

Quite recently, in the month of January, 1903, a young girl, M. C., appeared before the correctional court of the Seine, she having shot her brother-in-law, M. S. He had seduced her at the very beginning of his marriage when she was only sixteen years old. In the month of November, 1902, S. left his home to live with his sister-in-law, but she being on the point of becoming a mother he abandoned her. On the twelfth day of December M. C. went to find him at his home. A discussion commenced, during which S. pretended that he was not the father of the child, and immediately the young girl drew a revolver which she had hidden in her muff and fired at her lover, hitting him in the mouth. At the trial the girl declared that she had no intention of killing her lover. The Court, taking into consideration the circumstances of the case and the motive which had caused the accused to act, merely gave her two months' imprisonment. All this proves that the jury represents faithfully public opinion by acquitting, since magistrates themselves, when the occasion is presented, decide in the same way.

Another dramatic adventure took place at Marseilles a few years ago. An officer of rank in the army, without fortune, had the imprudence to give a taste of luxury to his daughter, whom he adored, and had given her the education of a princess. He had a married brother, a rich business man at Nice, but without children. The latter came to see his brother, the officer, and proposed taking his daughter with him to Nice. The father consented and the uncle started with his niece. She was pretty, vivacious and gay. His wife was no longer either pretty, or young. It was not long before he felt the charms of youth and beauty and he fell desperately in love with the girl. She, being very much spoiled by her uncle, who satisfied her luxurious tastes, and very sensible to the affection with which he surrounded her, the nature of which she did not understand, did not know how to defend herself against the plot of which she was the object. Her uncle, abusing her confidence and innocence, finally overcame her last scruples by promising her that her honor would be perfectly safe in the eyes of the world. However, pregnancy occurred and along with it her dishonor.

Upon learning this news her father died broken-hearted, and soon after this the mother killed herself. When the child was born the uncle wished to separate himself from his niece; after having wished to marry her he turned her out announcing his intention of placing the child in a foundling hospital. This project exasperated the girl. She bought a revolver; her lover allowed her to do so hoping that she would commit suicide, but this hoped-for event did not occur; she came to her uncle and reproached him for his dishonor, but the uncle merely shrugged his shoulders, saying that he did not like romance and that she was playing comedy. This reply was too much, and seizing her revolver she fired on her seducer and continued pouring bullets into him. Then, suddenly, her anger fell and love reappeared. She threw herself tenderly upon him and sponging away the blood covered him with kisses. The uncle died from his wounds and the young girl was acquitted by the jury.

In this case the existence of the child held a prominent place beside that of jealousy in the motive of the crime, and we will mention other cases where the future of the child was the cause of the crime committed by a woman on her lover, her husband, or her husband's mistress.

In 1880 Countess de T. appeared before the

jury, having supported with resignation and patience her husband's infidelities. He had as a mistress a young dressmaker, M. M., who did everything that was in her power to make herself odious to his legitimate wife. One of her favorite pastimes was to have herself called Countess, the title of her lover's wife. Countess de T. would, without a doubt, have continued her martyrdom in silence had she not learned of her husband's intention of marrying M. M. as soon as he was a widower or divorced. The thought that this girl would take her place and become the mother of her children made her absolutely beside herself, and she ended by disfiguring her by throwing vitriol in her face. To the jury she said: "I wished to disfigure this woman, not because she was my husband's mistress, nor because she covered my family name with dishonor, but for the reason that when I was dead she would become the mother of my children. . . . In a second the souvenir of all that I had suffered came upon me, the perspective of all the humiliation that was awaiting my poor children — all this made me crazy." The jury rendered a verdict of not guilty and she was acquitted.

This drama, which greatly worked up public opinion twenty-five years ago, shared the attention with quite another as celebrated, namely, the tentative at murder of her lover committed by Marie Bière. Here again we are dealing with a case of murder caused by maternal love and not by jealousy, with this difference, nevertheless, that Countess de T. wished to defend her children, while Marie Bière wished to revenge hers. Marie Bière was a young actress, and at the time she met M. G. she had already had several *liaisons*. He was a rich, skeptical Parisian. He was desirous of merely exchanging fantasies, so to speak. Soon afterwards they separated in a friendly way without any disagreement or scandal, as is the custom in a certain society, where one knows how to amuse oneself. M. G., however, was not aware of the exalted nature of the woman, and this little romance was the most serious event in her life. As soon as M. G. discovered this passion, he wished to break off all relations, because he was a well balanced man and feared scandal above all things.

On the contrary, Marie became more and more exalted and the birth of a child finally complicated the situation. For a time she had thought of having an abortion performed, but renounced the idea. After its birth the baby was sent to the country to be cared for upon the advice of M. G. The baby died from poor care, and then the idea of vengeance began to develop in the unbalanced mind of Marie. She decided to avenge her child because it died on account of the father's fault, and according to her own expression, she condemned G. to death and wrote this condemnation on the back of his photograph which she had in her possession. She met M. G., however, several times, but did not dare to execute her project, and it was only several days later, Jan. 7, 1880, that she executed her vengeance that she had planned more than a year previously.

Dr. Blanche, who examined the mental condition of the woman, concluded as follows: "When the accused fired at M. G. she knew what she did, but she was at the time under the influence of such passion and morbid excitement that it was very difficult for her to resist those sentiments which dominated her and obliterated her moral sense."

In both of the two foregoing crimes it would seem that the thought of the child was the determining motive, but it is quite certain that jealousy played an important part, especially in the last case.

Husbands will act, not only from jealousy, but also from the desire of avenging their honor. Without trying to justify this idea it should be pointed out that public opinion considers a deceived husband as dishonored. We do not wish to uphold a husband who kills his wife for adultery, His act is a crime, and although one may pity him, he should be condemned. Legislators have seemed to uphold the murder of the wife, for adultery, by her husband as excusable when the latter discovers her in the act. This excuse may perhaps be attributed to the idea that the legislator allows the husband to avenge his honor, because if it was a case of jealousy, one could not readily understand why this excuse should be reserved to the husbaand and not for the wife as well. A few years ago a husband killed his wife's lover and the trial showed that a short time before he had used threatening words which explained the motive of his crime: "I will take his life or mine; I must kill him, he dishonored me."

It sometimes happens that a husband obeys a less noble motive: he is afraid of being ridiculed and prefers to kill two beings in cold blood rather than to be joked about. This latter case assuredly can never claim the same indulgence as a crime from passion, but it is most evident that it would often be very difficult for a jury to recognize the two motives which caused the crime to be committed.

(To be continued.)

Reports of Societies.

AMERICAN PEDIATRIC SOCIETY.

NINETEENTH ANNUAL MEETING, WASHINGTON, D. C., MAY 7, 8 AND 9, 1907.

FIRST DAY'S SESSION.

THE USE IN PRACTICE OF THE THEORETICAL RESOURCES PROVIDED BY PERCENTAGE FEEDING.

DR. CHARLES HUNTER DUNN, Boston, said the chief step in advance had been the chemical recognition of the component elements of milk and the attempts to imitate nature as exactly as possible; the second great step was the recognition of the individual idiosyncrasies of each baby. The fact remained, however, that the subject of percentage feeding still presented difficulties to the general profession. The failure of modified milk feeding must be due either to limitations in the value of the resources or their improper application, and the writer suggested that it was due to the latter, and presented a plea for more careful use of the methods already in our possession. He thought the

difficulties due to two factors: the inherent unsuitability of cow's milk to the digestion of the infant, and the variability of the digestive powers of different infants. Too much stress had been laid upon the first and too little upon the second; we were too apt to attribute the chief rôle to the unsuitability of cow's milk. He referred particularly to the use of the so-called split proteid feeding, and thought that by using whey a very close conformity to human milk could be had. The cereal diluents, he said, contained starch, which was not indicated by nature as desirable for the infant, and in practice the giving of these diluents was often protested against by nature, although, of course, in many the starch would be digested. When the starch digestion function had been developed, of course they could be used. The same arguments as those against the indiscriminate use of cereal diluents were applicable to the widely advocated use of the alkalies, lime water, sodium bicarbonate, stearate, etc. Any of these artificial methods might have a place in certain individual cases, but must be due to the individual idiosyncrasies of digestion.

SOME CONCLUSIONS FROM OUR KNOWLEDGE OF THE PROTEIDS OF MILK.

Dr. Thomas S. Southworth, New York, spoke of the early misconceptions concerning the proteids of milk and the gradual steps of enlightenment which began only with chemical analysis. The endeavor was made to imitate breast milk closely by the so-called modified milk, but it was soon found that many infants were not able to digest the modified milk except when modified to each individual case. There were many difficulties in the way of knowing the composition of breast milk and therefore of comparing it with cow's milk, and our chief knowledge of cow's milk was derived from commercial, not medical, investigation. The writer referred to the close analogy between cheese making and human digestion of milk; the important compounds formed with casein by ferments, alkalies and acids, and the necessity for the recognition of these compounds, both as chemical entities and of the part they play in facilitating the digestion of cow's milk. The real difficulty in infant feeding was not with the digestion of casein, but of para-casein. Lactate of casein was readily digestible, as shown by the use of buttermilk, which had had less vogue in this country than abroad. Decalcified casein was easier of digestion, and sodium citrate made milk more digestible by decalcifying it. The writer thought a new departure was necessary if students were to learn to feed intelligently and be enabled to overcome the difficulties they met with in practice. An understanding was necessary of the physiological and the pathological digestion of the elements of cow's milk if empiricism was to give way to intelligent scientific methods in infant feeding.

CANE SUGAR FEEDING IN ITS RELATION TO SOME OF THE DISORDERS OF CHILDHOOD.

Dr. Charles G. Kerley, New York: This study was undertaken as the result of an impression the writer had received by the observation of many children that cane sugar was not without harm to many. There was a class of cases defined as sugar susceptibles, usually children of rheumatic or gouty ancestry, with one characteristic peculiar to all, — a tendency to recurrence and to chronicity. He included those who had recurrent persistent colds, asthma, urticaria, eczema, rheumatism and recurrent vomiting. Seventy-eight cases comprised the cases, 15 from his own patients, whom he had cared for from infancy. Recurrent vomiting in 8; eczema, 7; asthma, 4; frequent colds, 17; chorea, 11; rheumatism, 4; rheumatism and endocarditis, 6; urticaria, 2; recurrent bronchitis, 6. More sugar was taken than was for the best interest of the individual cases because of the craving of child life for sweets and because the sugar-eating habit is so easily acquired. In the majority there was sugar incapacity. When a child was presented for treatment, cane sugar was excluded from the diet and a small quantity of saccharine substituted. They very soon adapted themselves to the deprivation of sugars from cereals, and it did not appear to influence their well being or growth. In those suffering from rheumatism, recurrent vomiting, eczema and asthma there was also interrupted medication. The most satisfactory results were obtained in the affections of the upper respiratory tract. Absence from free sugar in the diet broke up the tendency to recurrent colds in children in whom the removal of the tonsils and adenoids had been without benefit. The writer concluded that free sugar was sufficiently toxic in certain individual infants to produce perversion of function, and in some to allow bacterial invasion, as in acute articular rheumatism and endocarditis.

Dr. Thomas Morgan Rotch, Boston, thought these investigations of Dr. Southworth's of great importance as tending to put the subject of percentage feeding on a proper basis.

Dr. Freeman, Boston, considered the use of whey fluid one of the most valuable aids in difficult cases, and thought it should be ordered from the laboratories where that was possible. It was important that it had been shown that these recurrent colds in children might be due to indigestion and not to exposure.

Dr. L. Emmett Holt, New York, had been following out Dr. Dunn's suggestions with reference to the routine use of whey mixtures for very young infants, and had been surprised to see how it relieved chronic constipation. The proteids could be raised gradually, the fats being kept low, with relief of indigestion and avoidance of troublesome symptoms. He agreed with Dr. Freeman that the mixtures should be ordered from the laboratories. He agreed with Dr. Kerley as to the ill effects of free sugar in the diet of many infants.

Dr. Charles G. Kerley had used the whey mixtures extensively for two years and felt that while it was a very useful measure, applicable in a considerable number of cases, it was by no means a solution of the infant feeding problem, its chief fault being that children did not gain on it. He thought it could not always be relied upon.

Dr. J. P. Crozer Griffith called attention to the recent studies upon the difficulty of digesting foreign albumins, and said the albumins of the cow were necessarily not the same and not so digestible as those of the mother; there were certain principles in the mother's milk necessary to the digestion of many children and they could not get along without it.

Dr. F. S. Churchill, Chicago, did not see how any one who had used the split proteids or whey mixtures could help being enthusiastic believers, because the majority of babies so fed invariably do well. Whey mixture was such a simple food that few babies could fail to digest it.

Dr. Walter Lester Carr, New York, said Dr. Kerley's statement was borne out by his own experience, that whey had a decided place in the feeding of premature infants and congenitally weak children, but that after using it for a time it seemed impossible to get a gain of weight. In eliminating the sugar it must be borne in mind that faulty oxidation might be one of the features.

Dr. Eaton deprecated the habit prevalent in some parts of the country of feeding babies according to a set of tables without regard to the individual idiosyn-

crasies. He had used the whey mixtures with great satisfaction.

Dr. Saunders had used the whey mixture for many years with great satisfaction. One of the mixtures with which he had had most rapid gain was that of whey and condensed milk.

Dr. Crandall's experience bore out what Dr. Kerley had said as to the use of the whey mixture.

Dr. Dunn, in closing, called attention to the fact that some of the cases that seemed to do well on condensed milk had done even better when fed on a laboratory prescription of the same composition.

Dr. Southworth added his testimony to the value of the split proteid feeding; he had had excellent results with it.

A CASE OF HEMATHORAX. ASPIRATION. RECOVERY.

Dr. W. P. Northrup, New York, reported this case, the patient having been seen three times by a well-known member of the society, who pronounced it bronchitis. He saw the case after the child had been ill two months. A poorly developed child of five months, pale, respirations 80 a minute; left chest flat; heart displaced to the right; no fever. Taking the infant on a pillow on its back nothing happened as long as it lay quiet, but when turned toward the right the child had an attack suggesting the cessation of all vital functions. X-ray showed the chest filled with an opaque fluid. Two ounces of a black fluid was aspirated, when the pulse improved and the heart returned to its normal position. The fluid was blood, which coagulated quickly in the bottle. A year after the aspiration the patient is doing well, the only cause for anxiety being rapid respiration.

ANOREXIA NERVOSA IN CHILDREN.

Dr. F. Forchheimer, Cincinnati, presented this paper, which referred to the several previously reported cases under somewhat different names, the condition having been usually looked upon as one of the manifestations of hysteria. According to the present state of our knowledge, we were justified in calling it a neurosis. As a rule, the children who have the disease have grown up without discipline, being allowed to choose their own diet.

Female, seven years, mother and father both neurotic; child always had its own way; at the age of six made up her mind that she would not eat but certain articles, practically nothing but cheese; none of the stigmata of hysteria were present; she was intelligent and consistent in her responses. Under proper treatment she soon recovered.

Female, aged twelve, mother and father neurotic; child brought up on artificial food; would eat only pickles and olives; if they tried to get her to eat anything else she vomited. Was very much run down, irritable and cross, backward in studies, cried easily and slept badly. Under proper treatment she gained fifteen pounds in a few weeks.

Male infant, one year of age, mother and father neurotic; father had had syphilis. Child had never been ill in any way; breast fed. From the ninth month attempts made to feed artificially. The child would not take any food. Was taken to the hospital and for four days nothing given by the mouth; then feeding began, but in vain; child would take water, but nothing else. Gavage used for two weeks, when the child recovered.

Boy three years old, only child of parents married late in life. Neither of the parents believed in disciplining the child. For some time the boy had been cutting off articles of diet until he would touch nothing for several days, except a piece of fried bacon or a piece of banana. Had a degree of emaciation that the writer had rarely seen surpassed. Three weeks later the child died from starvation. The writer believes all these cases could be cured by proper treatment and discipline, especial stress being laid upon discipline. Gavage should be held out as a last resource.

Dr. Charles G. Kerley, New York, had had a case of a four-year-old girl who always vomited food even at the table, but who, when allowed to eat in the kitchen, never had these attacks. The child was finally cured by removal to the house of her aunt and association with other children.

Dr. Putnam, Boston, had often succeeded in the milder forms of this disease by having the parents desist from saying anything about food or trying to force the child to eat.

Dr. J. P. Crozer Griffith referred to a case, a child of a physician, some months over a year of age, who could not be weaned and in which gavage had to be used, and now at the age of four they still had difficulty in getting the child to take food.

(*a*) THREE CASES ILLUSTRATING TYPHOID FEVER IN THE FIRST YEAR OF LIFE. (*b*) A CASE OF ARTICULAR RHEUMATISM IN AN INFANT. (*c*) A CASE OF CONGENITAL BILIARY CIRRHOSIS.

Dr. J. P. Crozer Griffith, Philadelphia, presented these cases: three cases of typhoid fever, one of five months and the other two of nine months. In the first case there was an excellent opportunity of studying the beginning of the temperature record, and death occurred from intestinal hemorrhage. There was absence of the step-like rise characteristic of the adult's chart. There was positive Widal, rose spots and enlarged spleen. In the second case, nine months, there was nothing unusual except the instance of relapse with the opportunity of studying the temperature from the beginning to the end of the relapse. It had been the custom of the mother when putting the baby in the tub to cleanse the mouth with the spigot water. Typical spots and enlarged spleen. Third case, nine months; ordinary course; rose spots and enlarged spleen; the history suggested the possibility of persistent house infection. The child was fed partly by breast and partly by unboiled cow's milk; the bottles had been boiled, but the nipples kept in unboiled cold water.

The case of articular rheumatism was a baby five months old, with rheumatism of hands and ankles. Treated with orange juice to exclude scurvy, without effect; under the use of salicylates it gradually recovered.

The case of biliary cirrhosis, five months old; jaundice said to have been present from birth; child lost weight steadily. After being brought to the hospital there was intense jaundice; liver much enlarged; everything possible done to make it gain in weight, but in vain. Black material passed from the bowel, which appeared to be decomposed blood. Child became steadily worse and died; autopsy showed typical cirrhotic liver with the duct of the gall bladder entirely obliterated.

Second Day's Session.

THE PRESIDENT'S ADDRESS: PSEUDO-MASTURBATION IN INFANCY.

Dr. B. K. Rachford, Cincinnati, read this paper, the detailed cases upon which it was founded containing the writer's own cases and a number reported to him by members of the society in response to letters addressed to them. In the discussion of the disease the writer considered age the most important etiological factor, and nearly all of the cases occurred in

female children. The anatomical and physiological condition of the organs of generation of the infant was considered in detail. The external genital organs were well developed in physiological function from birth, although the internal organs were not. For this reason there could be a syndrome complex closely resembling the sexual feeling. True masturbation occurred after the age of ten. True masturbation occurred oftener in males; pseudo-masturbation oftener in females. This might be due to the fact that the toilet of the female child was not as carefully looked after as that of the male, and the greater exposure of the external genital organs of the female. Later it could be classed among the habit neuroses. Environment was of the greatest importance in keeping up the habit. Heredity played a large part in establishing the predisposition, and gouty inheritance might be one of the predisposing causes. Acid condition of the urine had been found to be a frequent cause, as was also constipation. Of 52 cases presented, 25 were cured, and in only 2 was treatment of no avail. The writer was convinced that pseudo-masturbation occurring in children under two would in time get well under almost any form of treatment; the tendency was to spontaneous recovery. There was no connection between pseudo-masturbation in infancy and true masturbation in later life, though the former might tend to develop the latter. There was no connection between pseudo-masturbation and epilepsy, and the writer had never seen these two neuroses co-exist.

DR. JACOBI, New York, did not agree with the essayist that masturbation in infancy and childhood was not the same as the masturbation of adult life; he believed it should be classified with masturbation of more mature life. It showed itself by the same excitement, interrupted respiration, redness, staring eyes, large immobile pupils, perspiration and convulsive twitchings, as in the adult, and he looked upon it as the same condition.

DR. L. EMMETT HOLT, New York, referred to the frequency of the habit in mentally defective children, and considered it the rule with them rather than the exception. He thought the mental defect the cause rather than the result in these cases. He had not seen any case where the mental defect was traceable to the habit. He did not look with favor upon the appliances for mechanical restraint in these cases, nor upon the methods of stripping back the preputial hood. His cases had been nearly all in females.

DR. HENRY KOPLIK, New York, did not believe that true masturbation could exist in the infant because it presupposed intention and a resulting nervous explosion. He had found, as the other speakers had, that the great majority of cases were in females. He considered that the neurotic tendency was the chief factor.

DR. C. G. KERLEY, New York, was in accord with the views expressed in the paper, except that he thought that in cases over four years of age the prognosis was not so favorable. The cases were often discouraging and treatment had to be carried out for a long time. He exhibited an appliance for mechanical restraint that he had found useful.

DR. MAYNARD LADD, Boston, showed a device for mechanical restraint similar to that employed by Dr. Kerley, consisting of a long section with two cross bars, which kept the thighs about one and a half inches apart, while allowing free movement of the legs.

KERNIG'S SIGN IN INFANCY. A STUDY OF TWO THOUSAND CASES.

DR. JOHN LOVETT MORSE, Boston, presented this paper, in which he concludes that Kernig's sign is almost never found in infancy except in meningitis. That its presence in an acute disease justifies, so far as one sign can, the diagnosis of meningitis. That it occurs with equal frequency in all stages of the disease and has no connection with the degree of intracranial pressure. It has no value in diagnosticating between cerebrospinal and tubercular forms of meningitis.

DR. HENRY KOPLIK, New York, agreed with Dr. Morse that Kernig's sign as a diagnostic element in forms of meningitis in infants under two years of age is of very little clinical value. He said the sign should not be confused with a condition of myotonic contraction.

BACTERIOLOGY OF MENINGITIS.

DR. F. S. CHURCHILL, Chicago, read this paper. Only the known bacterial cases were reviewed. Six cases showed meningococcus; one case pneumococcus; one case pneumococcus in the spinal fluid; one case primary tubercle bacilli; one, Klebs-Loeffler bacillus; one case syphilitic; four undetermined cocci; four no organisms in the spinal fluid. The meninges, like other parts of the body, might be attacked by a variety of organisms; 80% of the trouble due to meningococcus. Next to the meningococcus, pneumococcus was the most frequent cause. Mode of access to the meninges through the throat and nose. Diagnosis between the different types could not be made from the clinical picture, but only from spinal puncture. Mixed infections were infrequent. The organism could be found in the nose and throat of healthy individuals living in close proximity to patients ill with meningitis, and these patients should be isolated. The meningococcic cases should always be quarantined and probably the pneumococcic ones.

GRIP MENINGITIS.

DR. SAMUEL S. ADAMS, Washington, reported this case. The child when first seen, being supposed to have an attack of indigestion, had a temperature of 106°, pulse 140, and the writer made the diagnosis of grip, which was confirmed by several eminent consultants. Complained of headache and of being tired. Blood examination showed nothing of importance. An otologist excluded any disease of the middle ear. Then Kernig's sign developed; symptoms of meningitis; lumbar puncture performed; two ounces of fluid withdrawn, which showed the presence of influenza bacillus. This was the first case reported by an American in which the diagnosis had been confirmed by finding the organism in the fluid of lumbar puncture.

DR. HENRY KOPLIK, New York, said he had before mentioned a case similar to this of Dr. Adams's and had since had another case.

DR. L. E. LAFETRA, New York, reported a case of tubercular meningitis with a terminal infection of pneumococcus; also a case in which at autopsy the influenza bacillus was recovered in the pus.

DR. L. LOVETT MORSE, Boston, disagreed with Dr. Churchill as to the necessity of isolating meningitis cases; he did not believe the danger of contagion was very great.

DR. HAMILL, Boston, reported a case in which the tubercle bacilli was isolated from the spinal fluid, with recovery of the patient. He agreed with Dr. Churchill as to the necessity of isolating these cases.

DR. JACOBI, New York, agreed with Dr. Morse that it was not practicable to isolate these cases.

CONGENITAL STENOSIS OF THE DUODENUM. REPORT OF CASE.

DR. H. L. K. SHAW and DR. LEON BALDAUF, Albany, presented this case of congenital stenosis of the duo-

denum, exhibiting photographs of the condition and the specimen. Child born after normal labor; twelve hours after birth passed miconium; placed at breast and vomited small amount of greenish fluid sometime later. During next two days vomited greenish fluid a number of times; seemed hungry and cried as if in severe pain; nursing discontinued and barley water and whey substituted; miconium and some brownish fluid passed. Operative procedure postponed in the hope that the condition might be spastic. Ten days after birth had lost 2¼ lb. Died thirteenth day after birth. There was stenosis of the bowel below the opening of the bile duct.

Third Day's Session.

THE CALORIC VALUE OF MODIFIED MILK IN ITS RELATION TO INFANT FEEDING.

Dr. Maynard Ladd, Boston, read this paper, which consisted of a series of cases studied by the writer in which the rate of growth in relation to the number of calories taken had been estimated. The series comprised twenty cases and tables were shown exhibiting the weight development. Great variation was noted between the calories taken and the gain in weight, and the writer concluded that the calories in the food of the infant in the first year of life could not be furnished by fats and proteids vicariously; that a given number of calories did not necessarily cause the same rate of growth, even when of the same age and development; that the caloric value of the food is not the most important consideration in determining the quality of the infant's food. Neither the number of calories nor the energy quotient, could be determined accurately.

Dr. L. Lovett Morse, Boston, considered the American method of feeding better than the German, but thought the good points should be taken from both. He estimated the food in calories from time to time chiefly to make sure sure in cases of difficult feeding that he did not get the total amount too low.

Dr. Henry Koplik, New York, called attention to the amount of waste in the gut, which he said was absolutely undeterminable. He thought that the percentage method was not the only way of feeding a baby successfully; in buttermilk feeding, even though the percentage food contained more calories, the waste in the gut in liberating the food was such that the baby might do better on buttermilk.

Dr. Freeman, New York, deprecated the tendency to feed the babies on proteids of less than 1%, and thought that if attention were paid to the matter of caloric values better standards would be obtained.

Dr. L. E. LaFetra, New York, emphasized the points made by Dr. Morse and Dr. Freeman and thought it would be enlightening if we could determine the lower limits of caloric value to be supplied by the proteids; the upper limits could be determined by the digestive capacity of the infant.

Dr. Thomas Morgan Rotch, Boston, protested against the habit of speaking of any method as an ideal method. Cases should not be treated with any on method alone. What should be insisted upon was that the method used should be exact.

A CASE OF MYXEDEMA.

Dr. George N. Acker, Washington, presented this case, which was a child healthy until eighteen months of age, when he presented it to the society in Raleigh in 1903; it was then a typical case of myxedema. It had been upon thyroid since and was now a well-developed child and in good condition. Gained seven inches during the first year; height now forty-one inches.

THE SYMPTOMS OF STATUS LYMPHATICUS IN INFANTS AND YOUNG CHILDREN.

Dr. John Howland, New York, had observed over twenty-five cases during the last year. No gland weighing less than 10 gm. was considered pathological, the average weight of the gland during the first two years being 6 gm. To be on the safe side he had included none weighing less than 15 gm. All the tissues of the body were hyperplastic, including tonsils and adenoids. The changes consisted of a hyperplasia of tissue normally present. Symptoms were, sudden death at beginning of anesthesia, administration of antitoxin, or the child might die suddenly in bed; another group, the characteristic symptoms were, with or without some indisposition the child becomes suddenly ill, rapid, gasping respiration, with cyanosis, attacks of convulsions, temperature in majority very high, 104.7°. The dyspnea not an obstructive dyspnea, but toxic in character. These cases were usually called acute congestive bronchopneumonia. A rarer form were those cases associated with purpura.

Dr. Blackader, Montreal, had had a very painful experience with one of these obscure cases, in which death had been attributed to change of nurses; autopsy showed a greatly enlarged thymus, 18 or 20 gm.

Dr. Thomas Morgan Rotch, Boston, said this was a subject the knowledge of which should be more widespread as the cases were often not recognized.

Dr. S. M. Hamill, Boston, was glad to hear the writer take the view that these cases were of toxic origin. There was great similarity between the condition and the infections — in the character of the dyspnea, its irregular nature, and in the cyanosis and convulsive seizures.

Dr. Howland, in closing, said he had not observed a case that had recovered, except the one in which the thymus acted as a foreign body, obstructing respiration.

A STUDY OF THE EARLY CONDITIONS OF OSTEOMYELITIS IN YOUNG CHILDREN BY THE ROENTGEN RAY.

Dr. Thomas Morgan Rotch, Boston, had been making a study of this condition by means of the x-ray, for he had concluded that delay in diagnosis, as in appendicitis, might mean death, or deformity that could not be remedied. To accomplish this early diagnosis the x-ray was of inestimable value, and in a number of cases it could only be diagnosed by that means. The x-ray should be used at once with the earliest appearance of the symptoms. Photographs illustrating the writer's remarks were shown, and he enunciated the importance of remembering that cases of osteomyelitis were not so rare, and that in most cases early operation was what would save the limb from deformity and, in many cases, save the child's life.

Dr. Samuel Adams, Washington, thought that in most cases the physician was more capable of making a correct diagnosis in these cases than the surgeon, and deprecated the habit of turning the cases over to the surgeon until every means of clinical diagnosis, including the x-ray had been utilized.

Dr. F. S. Churchill, Chicago, agreed with Dr. Adams as to the attitude of the physician towards the surgeon in these cases, and reported a case occurring in a girl of eight years, involving both tibia, both radii and the forehead, following in the wake of a severe typhoid. Typhoid Bacilli recovered from the pus at operation.

Dr. L. E. LaFetra, New York, emphasized the fact that these cases are not infrequent; he had seen ten in

in the last five years. Early treatment in these cases would save the limb.

DR. THOMAS MORGAN ROTCH, Boston, thought the expert opinion of both surgeon and laboratory man was of the greatest importance, and he had a very strong faith in the surgeon. It was only by a combination of all these opinions that the best results could be obtained.

A CASE OF CHYLOTHORAX.

DR. C. G. JENNINGS, Cincinnati, reported this case: a child, nine years of age, presented himself with dyspnea. An acute catarrhal affection some weeks before and following that persistent fever and symptoms that pointed to pneumonia. There were physical signs of pleural exudate, and it was thought to be a case of empyema. Aspiration revealed, instead of pus, chyle; first aspiration, 12 oz. Chest aspirated thirteen times and peritoneal cavity once. The child presented practically no symptoms when the fluid was not present. Tuberculin used without reaction. The fluid had all the chemical qualities of chyle and the microscopic picture was that of chyle.

THE NEED OF GREATER ACCURACY IN PRESCRIBING STARCH IN INFANT FEEDING.

DR. MAYNARD LADD, Boston, read this paper, which was designed to bring out one point,—the great indefiniteness of physicians in the use of the cereals. The paper presented a plea for more accurate methods of prescribing starches in percentages as with fats and proteids. In the barley water mixtures there was great variation in the amount of starch contained, and the inaccuracy due to this was responsible for many of the cases in which the child was not supposed to be able to digest starches at all. Formulæ varied from .64% to 6%. Using the minimum or maximum solutions as diluents the amount of starch varied from .51% to 4.8%. The rational thing to do was to give the minimum starch solution in the early months and gradually increase with the age. The Walker-Gordon Laboratories were now prepared to fill prescriptions in this way.

Book Reviews.

The Practice of Obstetrics by American Authors. Edited by CHARLES JEWETT, M.D., Professor of Obstetrics and Gynecology in the Long Island College Hospital, New York. Third edition, revised and enlarged. Illustrated with 484 engavings, 46 of which are in colors, and 36 colored plates. New York and Philadelphia: Lea Brothers & Co. 1907.

This third edition of Dr. Jewett's "Practice of Obstetrics" by 17 American contributors comes to us with several additions and improvements. The five chapters contributed by William S. Stone, of New York, have been rewritten. Each has an ample bibliography of the recent literature. A bibliography is to be found also with Vineberg's chapter on abortion and Williams's chapter on puerperal infection; the latter a lengthy and exhaustive treatise of some 47 pages. The portion on symphysiotomy has been revised and is now in most satisfactory shape, both as to matter and illustrations. Sections on vaginal Cesarean section and hebotomy have been added. The chapter on immediate repair of vaginal and vulvar lacerations is hardly specific enough as to operative details; intermediate repair is slighted and immediate closure of cervical tears is advocated in a not too judicial tone.

The book contains a good chapter on puerperal insanity by Allan McLane Hamilton. The hand of the accomplished editor is seen in many parts of the work so that it has more homogeneity than a majority of the "system books."

As to the bookmaking, a deleterious waste of space is to be noted For instance, the table of contents, instead of being printed in very large type and spread over five pages would be easier of reference if printed in smaller type on two pages; the 8 full-page plates, showing different forms of monstrosities placed between pages 336 and 337 might do for a monograph, but are out of place in a textbook. They add to the bulk and weight of the volume, already too great, and by separating the reading matter distract the reader's attention. Plate XX, a very badly colored representation of a vesicular mole, adds nothing to the engraving of the same subject on the following page, and should be left out.

Aside from such minor defects the book is a good one and should maintain its previous popularity.

Surgery of the Rectum. By FRED C. WALLIS, B.A., M.D., B.C., Cantab., F.R.C.S., Surgeon to Charing Cross Hospital, St. Mark's Hospital and the Grosvenor Hospital for Women and Children. New York: William Wood and Co. 1907.

Wallis has written a little book of 165 pages, which contains first and last a good deal of information, — some of it new. The author appears to have discovered the rectum. As he says in his preface, "the first five chapters contain my original views." That is the note of egotism which so permeates the book that the unsuspecting reader is tempted hastily to drop it among the coals. But in spite of errors in taste and a few errors in form the book contains much that is instructive. Wallis seems to have invented the term *ano-rectal ulceration*, a condition which he finds to lie at the bottom of *pruritis ani*, abscesses, fistulæ and other similar conditions. His artist supplies us with wondrous il ustrations of the crypts of Morgagni, the common seat of these ulcerations. Five chapters are concerned with ano-rectal ulcerations, and incidentally the reader is informed that he should attend certain clinics at the Charing Cross and St. Mark's hospitals. Those first five chapters comprise the important part of the book, while the remaining nine chapters deal in a superficial but perfectly coherent and intelligent fashion with such important topics as hemorrhoids, stricture of the rectum, malignant disease of the rectum, etc.

The book is certainly useful and probably is worth the $2.00 which the purchaser must pay for it.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, OCTOBER 3, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 Boylston Street, Boston, Mass.

THE DEVELOPMENT OF GRADUATE TEACHING.

An interesting phase of medical education at this time is the way in which it is extending its domain into the social and to some extent into the political fields. The function of a medical school is rapidly coming to be much more than the education of the individual student for the practice of his profession; in fact, there seems at times to be danger that this primary object may be lost sight of in the expansion which is now everywhere apparent. We have on various occasions commented on the significant part medicine is destined to take in the solution of some of our most knotty social problems, and also of the wide influence it is coming to have in shaping legislation; and it is to the medical schools of the country that we must look for the proper direction of these new and responsible activities.

Another field in which we may properly look for much development in the immediate future is the continued education of physicians in active practice by the medical schools. No one will venture to say that a man's education is complete who has successfully passed through a medical school, and much less will it be asserted that he can by any possibility keep intelligently informed of the progress of medicine, unless he devotes a certain time to the perfecting of his knowledge by other means than the experience of routine practice. To meet this demand within the ranks of the profession itself, graduate courses have been instituted and are in successful operation at many of our best medical schools. These courses are conducted not only during the winter months, but also in the summer, so that the needs of graduate students may be met practically at any time during the calendar year. The perfecting of these courses is one of the highly important functions of the modern medical school, only secondary to the adequate instruction of undergraduates for whom the medical school primarily exists. That there is room for improvement in this graduate teaching is evident, and this may be said entirely without disparagement to the excellent progress which has already been made. The practical branches of medicine are particularly well represented in the graduate schools. Clinical courses are abundant and excellent and serve a most useful purpose; but it is altogether unfortunate that physicians engaged in practice should not have an opportunity to learn what is being done in those branches which do not have so immediate a bearing upon practice, but which are nevertheless of fundamental importance to an understanding of the real problems of medicine. This problem is one of the most important and also one of the most difficult which graduate teaching has to meet. It is apparent that practitioners and many undergraduate students have neither the time and often not the ability to prosecute individual researches in the more theoretical departments of medicine; but it is regrettable that they should be cut off from the possibility of learning at first hand the results of others' investigation, and its bearing on the general problems of clinical medicine. Courses should therefore be given under the auspices of the fundamental branches of medicine, — physiology, anatomy, pathology, pharmacology and chemistry,—which will demonstrate the modern methods of investigation and bring into closer relationship the laboratory and the clinic. Such courses if sufficiently known among practitioners and advanced students and if given at convenient hours would certainly meet with response. The type of course, to which we refer is illustrated by one to be offered this winter at the Harvard Medical School, by Dr. W. T. Porter, professor of comparative physiology, on the "Circulation of the Blood," with demonstrations, open to graduates and such others as may care to attend. The aim of this course is to present in graphic form the result of recent research on this subject with such experiments as are necessary to demonstrate the principles at issue. Such a course as this forms a connecting link between the research laboratory and the working clinic, and should do its part towards filling the gap which exists in far too great a degree between the laboratory and the practical branches. There

is no question that a series of courses on the various laboratory subjects, the object of which is not original research on the part of students, but a demonstration of methods used, and their bearing on the clinical side of medicine, would do much toward a fuller education of physicians and toward a broader conception of the function of graduate teaching in general.

FUTURE POSSIBILITIES OF EXPERT TESTIMONY.

THE present widespread feeling of dissatisfaction with medical expert testimony lends an added interest to Prof. Hugo Münsterberg's suggestions for a possible means of reform. In the September and October numbers of *McClure's Magazine*, Professor Münsterberg contributes articles on the possibility of applying psychological tests in the determination of the credibility of witnesses, and thereby relieving in a measure the present unfortunate state of contradictory evidence. We question whether the means propounded of accomplishing this desirable end will meet with the approval of the legal profession, and whether the time-honored method of cross examination in open court, before a jury, whose main attribute must be common sense in the estimation of testimony, whether of fact or opinion, will forthwith give place to the subtle analysis of the psychologist; nevertheless, such papers as these of Münsterberg are highly suggestive and should not lightly be passed by. The hope expressed in these articles is that the capacity of witnesses for correct observation and similar essential qualities of mind may be determined by psychological experiment, to the manifest advantage of a fair trial.

To substantiate the contention that witnesses of equal honesty may see and in general observe things in a very different way, Münsterberg instituted a series of experiments with his students at Harvard College, which certainly go far toward clearing up many inconsistencies which every trial brings out, and which are often put down to deliberate falsifying on the part of witnesses. In general, it appears from this final series of experiments that the important matter to determine is whether a given witness is capable of correctly recording his sense impressions or, to put the matter in plain language, to what degree he has the power of correct observation, evidently a matter of prime importance in the determination of many matters upon which a jury is finally required to pass judgment. The various inconsistencies of apparently equally honest witnesses are shown to be a natural consequence of varying powers of correct observation. It would therefore further the cause of justice, according to Münsterberg, if through tests at the hands of an expert psychologist, the credibility of a witness could be determined before he appears on the witness stand, to the end that his statements when under oath might then be taken at their true worth. Such a plan is chimerical at the present time, but it is not to be questioned that if the object of a trial is to reach the truth, as far as humanly possible, it becomes evident that no legitimate means which may conduce to that end should be disregarded. Münsterberg believes that experimental psychology has finally reached a stage of development where it may take an active part in the practical affairs of life.

In the second article to which we have referred, entitled "The Third Degree," Münsterberg propounds an ingenious method of getting at the inner life of criminals, and thereby inducing confessions and determining veracity by means of the association of ideas and reaction time. Examples are given which go far toward showing that the secrets of the human mind may be revealed by a comparatively simple method of testing the reaction time of various associations. A case of particular interest is that of a now notorious, self-confessed murderer, who recently figured as the chief witness in a widely advertised western trial, and whose testimony was discredited by the jury, leading to the acquittal of the defendant. By the tests which Münsterberg was permitted to use on this person, he arrived at the definite conclusion that the witness was telling the truth, an opinion which unfortunately found its way into the newspapers before the termination of the trial. Here was a case of great moment in which the common sense of a jury was entirely at variance with the results of scientific tests; naturally, the opinion of the jury prevailed, leading to the discharge of the prisoner.

It is evident that the question involved in this matter is one which must be fairly met. It is essential that our courts of law in their treatment of expert opinion do not depart from precedents long established, except for most sufficient reasons. On the other hand none can observe the present state of affairs, without wishing most cordially for a simple and more definite method of arriving at facts than we now have. It is certainly not impossible that experimental psychology may take a hand in the reform which is demanded on every side. These articles of Professor Münsterberg should be read and pondered.

MEDICAL NOTES.

Cholera in Japan. — Cholera has appeared in Japan, and 1,500 cases were reported up to Sept. 25.

Cholera in Russia. — It is reported that an epidemic of cholera which broke out along the Volga in Russia is spreading and already affects twelve provinces. The deaths are said to reach into the thousands with the greatest mortality in the more thickly populated regions.

Plague in San Francisco. — Dr. Rupert Blue, of the Marine-Hospital Service, and President William Oppuls, of the City Board of Health, are reported to have issued the following statement regarding the plague situation in San Francisco:

"From our knowledge of plague, the prevention of a sudden outbreak in epidemic form can be predicted with assurance; but a certain number of cases will continue to occur for a considerable period in spite of all preventive measures."

Up to the present time there have been upwards of 25 deaths and more than 40 identified cases.

Report of Henry Phipps Institute. — The third annual report of the Henry Phipps Institute for the Study, Treatment and Prevention of Tuberculosis, including Work Done during the Year from Feb. 1, 1905, to Feb. 1, 1906, has been published. The volume is 410 pages in length and enters into much clinical and pathological detail concerning the problems of tuberculosis. This report forms a valuable epitome not only of what has been accomplished by this institute in the investigation of tuberculosis, but also illustrates the possibilities of research in the great field of this one disease.

The Death of Prof. W. O. Atwater. — In the death of Prof. W. O. Atwater, of Wesleyan University, which occurred recently, this country loses a man who has made for himself an enviable reputation in popularizing science. He was sixty-three years old at the time of his death, and for many years had been associated with Wesleyan University. He early became interested in chemistry, particularly in its relation to agriculture, and later took up the study of foods and nutrition, with which much of his later work is identified. He held many public posts, and showed extraordinary ingenuity in carrying out his experimental researches. Perhaps his best known work is that relating to the food value of alcohol. In spite of the extraordinary opposition which his view met at the hands of certain religious organizations and temperance societies, he continued to maintain that alcohol had a certain food value. He was much beloved by those with whom he was brought in contact.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Oct. 2, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 28, scarlatina 39, typhoid fever 26, measles 10, tuberculosis 60, smallpox 1.

The death-rate of the reported deaths for the week ending Oct. 2, 1907, was 16.94.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Sept. 28, 1907, was 200, against 187 the corresponding week of last year, showing an increase of 13 deaths and making the death-rate for the week 17.11. Of this number 101 were males and 99 were females; 196 were white and 4 colored; 135 were born in the United States, 62 in foreign countries and 3 unknown; 41 were of American parentage, 137 of foreign parentage and 22 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 40 cases and 1 death; scarlatina, 51 cases and 1 death; typhoid fever, 23 cases and 1 death; measles, 12 cases and 0 deaths; tuberculosis, 69 cases and 18 deaths; smallpox, 1 case and 0 deaths. The deaths from pneumonia were 19, whooping cough 0, heart disease 10, bronchitis 4 and marasmus 11. There were 14 deaths from violent causes. The number of children who died under one year was 60; the number under five years, 71. The number of persons who died over sixty years of age was 39. The deaths in public institutions were 61.

There were 3 cases and 1 death reported from cerebrospinal meningitis during the week.

Tuberculosis at the Long Island Hospital. — For many years the almshouse hospital at Long Island, Boston Harbor, has been overcrowded with tuberculous patients to the detriment of those suffering from other diseases. This matter has again come up for discussion, and it is to be hoped that unless separate buildings are provided for this class of cases at Long Island, the Consumptives' Hospital's trustees will take as early measures as possible to relieve the present congestion at Long Island.

NEW YORK.

DR. A. W. FERRIS APPOINTED STATE COMMISSIONER IN LUNACY. — Governor Hughes has appointed Dr. Albert Warren Ferris, of New York, President of the State Commission in Lunacy, in the place of Dr. Charles W. Pilgrim, resigned.

STADIUM AT SYRACUSE UNIVERSITY. — During the coming month Syracuse University is to have the formal opening of its great new stadium which has been in the course of erection for the past two years and which represents an outlay of $600,000. The aim of the university authorities is to have the most complete athletic plant in the world, and with this end in view a gymnasium costing $400,000 will be built at the east end of the stadium. This large expenditure for the promotion of athletics has been rendered possible by the generous gifts of John D. Archbold.

OPENING OF COLUMBIA UNIVERSITY. — The opening exercises of the one hundred and fifty-fourth year of Columbia University were held on Sept. 25, when Prof. James Rignall Wheeler delivered the annual address, on "The Idea of the College and the University." At the opening of the medical department, the College of Physicians and Surgeons, on the following day, Dr. George S. Huntington, professor of anatomy, made an address upon "Methods and Scope of Natural Object Teaching in the Medical Course."

SEPTICEMIA WRONGLY ATTRIBUTED TO VACCINATION. — Walter Brown, seven years old, a boy in Brooklyn, died from blood poisoning on Sept. 23, about two weeks after he had been vaccinated in order that he might be allowed to attend public school, and Dr. George D. Barney, his physician, who seems to have reasoned "*post hoc, propter hoc*," refused to sign a death certificate, claiming that the septicemia was due either to impure virus or lack of precautions in performing the vaccination. The Health Department, at whose office the boy was vaccinated, at once investigated the matter, and as the result the chief medical inspector in Brooklyn stated that the death was undoubtedly due to outside infection, for blood poisoning would have developed within three days had it been contracted at vaccination. It was surprising, he said, that, considering the carelessness of parents and children, so few accidents occurred. As many as seventy children were vaccinated from the same bottle as Brown, and hundreds from the vaccine from which this was taken. The virus used by the Health Department is prepared with great care in the department's own laboratory, and in each case of vaccination a new needle and a fresh orangewood stick are employed.

STRAUSS PASTEURIZATION PLANT FOR BRUSSELS. — Nathan Strauss, of New York, who has been attending and taking part in the International Milk Congress at Brussels, has donated a complete pasteurization plant to the city of Brussels. On Sept. 15 the fifteenth summer season of the Strauss pasteurized milk depots in New York was closed. This year there were seventeen of these in operation, the city authorities having co-operated with Mr. Strauss to the extent of furnishing some of the booths from which the milk was dispensed. All the milk stations in public parks and on the recreation piers have now been discontinued for the season, but six of the stations, as has been customary of late, will be maintained throughout the year. These are situated at various points in the most crowded tenement districts of the city.

A HOSPITAL FOR CHINATOWN. — Chinatown is to have a hospital of its own, where the Chinese patients will have Chinese nurses and Chinese physicians to attend them, under the supervision of an American physician. The building is to cost $25,000, and a committee of Chinese merchants will secure the funds. For the last three years the Chinese merchants of the city have been supporting a hospital on Park Street, without the necessary authorization from the state, and recently John S. Cooper and Champe S. Andrews, legal representatives of the Medical Society of the County of New York, paid the hospital a visit. They were politely received by the superintendent, who informed them that there were fifteen physicians on the staff of the institution, all of whom had received certificates from the Chinese consul. Mr. Cooper has authorized the following statement, giving the results of this visit: The consul was, according to his own belief, acting within his rights when he gave out these certificates to the fifteen Chinese doctors. Everything in the matter has been done in the most amicable manner. The consul has recalled all the certificates, and the doctors, who are not ignoramuses by any means, will go before the Medical Board to pass their examinations in the orthodox manner. At present the Park Street Hospital, which is a substantial four-story building, is being remodelled and will be used until a suitable site can be found for the new hospital. The institu-

tion is supported by the Chinese merchants living in Chinatown; they are doing their best to fight the opium habit, and they are the only people in this country who can do it. The whole question has been put before the State Board of Charities, the authorities in Washington, and the district attorney here, and they have all decided to leave the matter in the hands of the County Medical Society to see that the hospital is conducted on established lines for the health of the city. There are now two or three qualified Chinese physicians in New York who can carry on the work until the other men receive their certificates from the board. The whole thing has been very creditable to the charity of the Chinese merchants to the poor of their race, who receive everything free in the hospital.

Obituary.

JOEL W. HYDE, M.D.

DR. JOEL W. HYDE, a prominent gynecologist of Brooklyn, N. Y., died on Sept. 22. He was born in Westbrook, Conn., in 1839, and was graduated from the Yale Medical School in 1861. In the Civil War he served on the staff of Major-Gen. Rufus Saxton and was afterwards surgeon of the 29th Connecticut Regiment, in which capacity he was present at the surrender of Richmond. After settling in Brooklyn he was appointed Brigade Surgeon of the National Guard of New York. For a number of years he was surgeon to the Brooklyn Orphan Asylum and chief medical adviser of the Ætna Life Insurance Company of Hartford and the National Life Insurance Company of Vermont. He was also gynecologist to St. Mary's Hospital, and in 1901 was elected president of the Brooklyn Gynecological Society. At the time of his death he was consulting obstetrician to the Long Island College Hospital and consulting gynecologist to the Bushwick Central Hospital. One of his sons is Dr. Clarence Reginald Hyde, of Brooklyn, also a well-known gynecologist.

6. PEDERSON, V. C. *Instructions to Those Having Syphilis.*
7. JACKSON, A. H. *The Determination of Sex: Is it Subject to the Law of the Survival of the Fittest?*

4. Von Ruck summarized the results of sixteen years' treatment of tuberculosis with tuberculin. He has for many years observed no bad effects from the treatment, but rather great benefit. The products of the tubercle bacillus act in a truly specific way by inducing antibacterial or anti-toxic immunity. The limitations of the treament arise from degeneration of tubercular tissues and associated exudative and productive inflammations. The specific treatment will arrest the action of the bacilli and prevent further degenerative changes, but it will not restore advanced changes or remove necrotic tissue or inflammatory products. It cannot remove the bacterial bodies from caseous tissue, or prevent softening and exfoliation. The author tabulates his cases, of which he has treated 1,893 in the past sixteen years, and compares them with a series of cases treated by private physicians. As to the permanency of his results, in the first stage 91.4% have not relapsed. Of the second stage cases, 80.4% have had lasting results. Of the third stage cases, 37.4% are still living in good health.

4. Halstead found a transitory glycosuria in 6 out of 44 simple fractures. The amount of sugar was never over 1% and did not seem to affect union. In six cases of fracture of the vertebræ he found glycosuria in three. A transitory glycosuria is not uncommon after infections with the ordinary pus micro-organisms, as carbuncle and erysipelas, especially when associated with gangrene. This glycosuria clears up under proper drainage, etc. Major operations with general anesthesia are contra-indicated while there is sugar in the urine. He advises a restricted diet. The prognosis is not affected by the glycosuria. In operations on diabetics, coma is the great danger. This is much more frequent after general anesthesia, so local anesthesia is always to be preferred. Spinal cocainization he prefers for leg amputations for diabetic gangrene. If possible a thorough course of medical treatment is desirable before an operation. The presence of acetone and the ammonia compounds is of more importance than the amount of

sugar. One case is on record of a fatal coma coming on after operation, in a patient who had been sugar free for two years.

9. Cannon and Murphy take up experimentally dynamic ileus, *i. e.*, ileus with the syndrome of occlusion of the bowel, without, however, closure of the lumen, as opposed to mechanical ileus, in which there is an actual occlusion of the bowel. The method employed was to observe the passage of food mixed with bismuth along the intestine by means of the x-ray. The animals used were cats. They crushed testicles or ovaries in their animals and found marked retardation of discharge of food from the stomach and sluggish movement of food through the small intestine. However, if the splanchnic nerves are cut, and then the testicles crushed, peristalsis is normal. Hence they conclude that ileus paralyticus can be produced without changes in or about the intestinal wall and that the condition is one of inhibition conveyed by the splanchnic nerves. They manipulated the stomach and intestines of animals and found a similar sluggishness. Cutting the splanchnic nerves before manipulation had no effect. Hence they assume that ileus paralyticus is not necessarily the consequence of reflex inhibition, but can be entirely explained as due to disturbances of the local mechanisms in the wall of the gut. They found that aloes mixed with the food produced no change in the ileus due to local manipulation. Physostigmine seemed to cause a very marked but only temporary increase of peristalsis in animals whose intestines were paralyzed by reflex inhibition, *i. e.*, whose testicles were crushed.

11. Contradictory to the usual belief that the intestinal contents in typhoid fever are swarming with typhoid bacilli, Pratt, Peabody and Long, using improved methods, were able to isolate typhoid bacilli from the stools in only 17 out of 100 cases of undoubted typhoid fever, or 17%. [R. I. L.]

THE LANCET.

SEPT. 14, 1907.

1. TREVELYAN, E. F. *The Co-ordination of Post-Mortem Work with Clinical Observation.*
2. FOXWELL. *An Address on Inhalation.*
3. *IWAI, T. *A Statistical Study on the Polymastia of the Japanese.*

8. PETERS, O. H. *Irregularity of the Pulse in Diphtheria.*
9. SPENCER, W. G. *Results in Appendicitis treated by the Immediate and Complete Operation.*

3. Iwai has made a careful and complete statistical study of polymastia among the Japanese. He gives an exhaustive bibliography, and concludes that among the Japanese, unlike western people, polymastia is generally found above the normal breasts, and most commonly on the anterior wall of the axilla; in many cases, especially in males, the areolæ are pigmented. The frequency of polymastia is about 1.68% in males and 5.19% in females. It occurs on the left more than on the right. It is inherited and in most cases transmitted by mothers. In perfect specimens the secretory process begins at the time of parturition and sometimes continues for six months. Six is the largest number of glands yet found on one person.

5. Short reports in detail 5 cases of actinomycosis of the appendix. About one hundred and fifty cases up to date have been reported. As regards etiology, a farming life, or one having to do with corn, seems to play a part. There may be extensive ulceration of the mucous membrane with or without thickening and usually ending in perforation. Before perforation has occurred diagnosis can only be made by finding granules in the stools. If in a patient over fourteen years of age there is a history resembling appendicitis, and a large, very hard mass adherent to the deep structures, with only slight fever and pain, and little or no vomiting, actinomycosis should be strongly suspected. If in addition the skin is thickened, edematous, shiny and of a purple tint, the probabilities are very great. Abscess and sinus formations are very characteristic. The prognosis is very grave. Operation should be as complete as possible. [J. B. H.]

2. Boyce reviews the work leading up to the use of atoxyl and mercury in treating sleeping sickness. Inorganic arsenic produced no permanent cures, the patient dying either of the protozoan infection or of too much arsenic. Atoxyl alone, while a tremendous improvement, was not satisfactory in many instances. Atoxyl combined with mercury, however, destroys both forms which occur in the life cycle of the trypanosome.

10. Somerville believes that high-frequency currents have a very considerable effect on the urinary system. He gives the details of several cases where the total twenty-four-hour amount of urine has increased under this treatment. He thinks that such currents improve the metabolism, and that the good results obtained from their use are not merely due to mental effect.

11. The cryptoscope is an ingenious apparatus by which a kidney exposed at operation can be thoroughly searched by means of the x-ray, and the smallest fragment of a stone discovered. This can then be removed by a small incision, instead of the large exploratory incision of the past. [J. B. H.]

THE PRACTITIONER.

11. TURNER, J. G. *Review of Dental Surgery.*

3. Grünbaum goes over the leading signs and symptoms of Addison's disease, and urges an earlier diagnosis. The pigmentation must be differentiated from that of (1) pregnancy, (2) chronic tuberculosis, (3) Vagabond's disease, (4) Von Recklinghausen's disease, (5) hemochromatosis, (6) exophthalmic goiter, (7) arsenic, (8) argyria, (9) the effects of heat, and (10) of workers in certain chemicals. The asthenia is very typical, and with an ergograph is easily demonstrated; blood pressure is invariably low; the blood itself shows few changes, but by means of the opsonic index some additional information may be gained.

5. Movable spleens are rare. The conditions leading to this anomaly are, in general, (1) enlargement, (2) relaxation of the splenic ligaments due to congenital or acquired defects, (3) trauma. It is more common in women who have a relaxed abodminal wall. Moorhead reports a case in which the diagnosis was only made at operation. Twisting of the pedicle may cause great variations in the size of the tumor. Opinions are about equally divided as to methods of treatment between splenectomy and splenopexy. [J. B. H.]

8. NASH, J. T. C. *Disinfection and Disinfectants.*
9. GOMPERTZ, R. H. C. *Case of "Hour-Glass Stomach."*

1. Barker advises the use of light local anesthesia in removing thyroid tumors. He uses β-Eucaine, .2%, to which is added some adrenalin chloride. The injection should be into the skin, not under it. It is a mistake to operate before at least a half hour has elapsed after the last injection. Morphia before operation is of value. He gives the details of his operation, with plates, and reports 22 cases.

4. Clogg believes that the hernial sac in children is congenital in every case and never acquired. It is difficult to believe that cure can be obtained in any other way than by removing the sac. Trusses and other appliances do not cure. The earlier operation is done the better. This should be, in breast-fed babies, immediately after weaning, and in bottle-fed, if healthy, at two months. His operation differs in no way from that done on adults. Cases of hernia of cecum and appendix, hernia of the bladder, hydrocele in relation to hernia, inguinal hernia in the female child, tuberculosis of the sac and strangulation are also reported. [J. B. H.]

7. TURNER, A. L. *A Case of Lupus of the Larynx Successfully Treated by the External Application of the X-Ray.*

1. Duckworth believes that so-called temperance parties and workers are misnamed; that they are not striving for a temperate, moderate use of alcoholic beverages, but for a total abstinence. The moderate drinker has, until recently, been held in disrepute by extremists of both kinds. While, undoubtedly, there is a class of people who are totally unfit to use alcohol in any form, there is left a vast majority in which a moderate use of alcohol does no harm. He thinks that it is by a broad education along commonsense lines that the most good can be done.

4. Poynton describes the various forms of arthritis in early life. Gonococcal arthritis, though rare, sometimes occurs in marasmic children from a gonorrheal ophthalmia. It is much more serious than in adults. Septic arthritis may occur as in adults. Meningococcal arthritis is not rare during epidemics of cerebrospinal meningitis. There is also a rare form of acute tubercular arthritis. He also briefly describes Still's disease, and the arthritides associated with syphilis and hemophilia.

8. SOMMER AND DANNEMANN. *History of the Medical Faculty of the University of Giessen.*

2. A moderate grade of sclerosis in the smaller arteries of the lung not infrequently occurs in mitral stenosis and pulmonary tuberculosis, but causes practically no symptoms. Primary sclerosis of severe grade in the smaller pulmonary arteries is extremely rare. Only two such cases have been reported: one by Romberg, the other by Aust. The authors report two cases, with pathological examinations; the first being an extensive and severe sclerosis, affecting the arteries of the pulmonary circulation only, with narrowing of their lumen and consequent increase of blood pressure, and hypertrophy and dilatation of right side

of the heart, causing dyspnea, great cyanosis, pulsation in veins and liver, edema, and finally death. The second case was a thrombus formation with partial organization on the site of sclerotic changes in the pulmonary artery. Both these cases, as well as the two previously reported, occurred in young individuals, the oldest being thirty-three years. It is probable that the degenerative changes in these cases were brought about by some congenital defect in the arterial walls of the pulmonary circulation, as there was no evidence of sclerosis elsewhere.

4. Leutert concludes that the congestion treatment is useless in chronic middle ear diseases. In acute suppurations after scarlet fever and measles it may be of benefit when employed after operation.

5. Hirschfeld and Kothe report nine cases of severe infections, mostly appendicitis or peritonitis, in which the leucocyte count rose to between 60,000 and 92,000. Of these six died. Eight were of the female sex. Myelocytes were present to about 7% in all the cases. The morphological condition of the blood and blood-forming organs in cases of abnormally high leucocytosis in severe infectious diseases needs much further study. The authors think these high counts are much more common than is usually supposed. [L. G. M.]

7. SCHINDLER, C. *An Improvement of the Neisser Suspensory.*

2. Halberstaedter and Prowazek describe further the cell inclusions which they have seen in cells taken from the conjunctiva of cases of trachoma. These inclusions the authors believe to be micro-organisms, because they have a distinct, characteristic and constant appearance. They have been able to produce the disease experimentally in orang-outangs. In the case of other animals, such as guinea pigs, rabbits, and other apes, the experiments were negative.

3. The authors review what has been accomplished with the hemolytic blood test for syphilis, and give their experience in 39 cases, of which 27 were positive and 12 negative. Much further experience is necessary to determine its clinical value, but they believe the test may lead to a better comprehension of the pathogenesis of tabes and paralysis, although negative findings are not conclusive evidence against the presence of syphilis.

4. Nagelschmidt thinks the high frequency currents of great value in local conditions, such as warts and epitheliomata, which can often be cured by a single application of a prolonged shower of sparks. Local applications are also made for psoriasis, eczema, neuralgia, neuritis, sciatica, sprains, inflammations, colitis, etc. Constitutional conditions, as rheumatism, gout, diabetes and arteriosclerosis are among those which have yielded in a marvelous manner to this treatment in the authors' practice. [L. G. M.]

No. 33. AUG. 15, 1907.

7. *LISSAUER, A. *Tuberculin Suppositories.*

5. Ogata and Ishiwara, in a communication from the hygienic institute of Tokio, give the results of their investigations of Tsutsugamushi disease. This affection is also known as the inundation fever of Baelz. The authors isolated a protozoan organism from the ulcers which are so frequently met with in this disease, which they describe fully. The organism has been cultivated, and the disease transmitted to animals by inoculation.

7. Since early in 1906, Lissauer has made use of tuberculin suppositories, in the treatment of 40 cases of tuberculosis at all stages of the disease. The prognosis for a cure was unfavorable in most of the cases. The tuberculin was placed inside of hollow suppositories, in doses varying from 0.5 mg. to 25 cg. These were given sometimes daily, and sometimes at intervals of one or more days. The results obtained were equal to those following the use of tuberculin by mouth. No local reaction was caused by the suppositories, except occasionally a little itching which was easily controlled. The author administered tuberculin by mouth in gelatin capsules in two cases of advanced phthisis, but could see no beneficial result. [L. G. M.]

2. Plaut reviews the work of Wasserman, Neisser and Bruck on the presence of antibodies and precipitives in syphilitic and parasyphilitic blood sera. In a series of 44 patients with general paresis, the author found, in all but one, a positive reaction in the spinal fluid. In the one case, the blood serum gave a positive reaction, though the spinal fluid was negative. In two cases, the first examination of the fluid was negative, but a later one showed a positive result. The intensity of the reaction bore no relation to the intensity of the process. The same condition of the spinal fluid is to be found in tabetics. Plaut has examined a number of cases of meningeal and cerebral syphilis, without finding this reaction present. Though the number of these latter cases are too few to base rules upon, it seems undoubted that a specific serum reaction is constant in general paresis and in tabes.

4. Löhlein sums up Wright's opsonin theory, and the interesting therapeutic results which have been gained in vaccine therapy. He doubts if Wright's theory is quite correct, and as far as he has been able to judge, thinks the opsonin is the same as the normal amboceptor of the German theory. This, however, must be looked into further before proved.

5. Pankow reviews the pathology, both macroscopic and miscroscopic, and points out that a large number of macroscopically normal appearing appendices show microscopically marked pathologic changes. He claims that appendicitis is far commoner than supposed, and says that 60% of all women coming to gynecologic operations in his clinic have had appendicitis. In many cases of chronic salpingitis, the author believes the appendix to be the etiological

factor, especially in cases of sterility due to adhesions. In these latter cases merely freeing the adhesions has led the way to a successful pregnancy. When tuberculosis and gonorrhea can be definitely ruled out, appendicitis is the probable cause of such conditions, for it is possible for a very severe inflammation of the appendix to pass almost unnoted. Many cases of so-called neuralgia of the ovaries are due to old adhesions from appendicitis. With all these points in mind the author strongly recommends the removal of the appendix in all gynecologic operations requiring laparotomy.

13. The authors carried out a series of observations by means of the orthodiagraph before and after excessive exertion in swimming contests, requiring a maximum exertion for a short period. In 10 out of 11 contestants examined they were able to demonstrate an actual diminution in the heart area after the contest instead of a dilatation. This they consider an "acute diminution." Accompanying this there were rapid, small pulse, dyspnea and cyanosis, as would be expected after such exertion. The contestants were for the most part in excellent physical condition. The authors consider this condition to be due to a dilatation of the peripheral vessels of the muscles under the influence of the exertion, a smaller amount of blood than normal coming to the heart at each diastole. In 7 out of the 11 cases albumin appeared in the urine. In 2 sugar was present. They conclude from the above data that swimming is one of the severest exercises, and that most careful training should precede the contest.

Berliner Klinische Wochenschrift. No. 28. July 15, 1907.

1. *Oppenheim, H., and Borchardt, M. *Two cases of Tumor of the Cerebellum; Operation; Recovery.*
2. Babes, V., and Vasiliu. *The Treatment of Pellagra by Atoxyl.*
3. Walliczek, K. *Hyperostosis of the Upper Jaw.*
4. Grosse, O. *Improvised Asepsis.*
5. Blumreich, L. *Gangrene of the Cervix in Abortion and its Significance.*
6. *Helbron. *Tuberculosis of the Eye and Its Treatment.*

1. (I) Oppenheim reports two cases of cerebellar tumor with operation, the first in a man of twenty-six years, in previous good health. There were present headache, especially in the occipital region, vertigo, vomiting, deafness of the right ear, cerebellar ataxia, slight nystagmus, shrinking of the field of vision on the right, absent corneal reflex, slight changes of sensation over the right side of the face, paresis of the facial nerve on the right, and slight ataxia of the right arm. A diagnosis was made of tumor in the posterior fossa of the skull, probably of the cerebellum, and a radical operation was performed. The tumor was a fibroma. Two days after operation, all the symptoms had improved, but the ataxia of the arm had increased. The patient was seen about five months later, and was without symptoms. The second case showed the following: total blindness, total left facial paralysis with reaction of degeneration, left auditory nerve affected, slight paresis of the pharynx on the left side, slight nystagmus, and limitations of movement of the left eye. Here a diagnosis of the tumor in the posterior fossa, involving the roots of the facial and auditory nerves, was made. This was also proved by operation. The tumor was removed with a small piece of the cerebellum. Three weeks later severe bulbar symptoms arose, which necessitated feeding through a stomach tube. Also marked tremor and ataxia of the left side appeared. The bulbar symptoms slowly disappeared, but the blindness and facial paralysis did not recede. The cerebellar symptoms still remained. In this case, the process was too far advanced to hope for complete recovery, but life was saved.

(II) Borchardt describes his technique in the above operations. Six such operations have been performed by him, and three patients are still alive. He finds that removal of small pieces of the cerebellar tissue, though followed by temporary increase of symptoms, are of no moment in the long run.

6. Helbron describes minutely all the forms of tuberculosis of the eye. He points out that in many cases the diagnosis cannot be made from the clinical appearances. He recommends removal of suspicious glands in the preauricular or submaxillary region, and animal inoculation, or the tuberculin test. The treatment should be local as well as general. When possible all tuberculous tissue should be removed. Tuberculin T. R. has been tried with little success. The new antituberculosis remedy, tulase, has been tried of late, but sufficient time has not elapsed since its introduction to permit a judgment as to its efficacy.

[R. D.]

Miscellany.

THE MARY PUTNAM JACOBI FELLOWSHIP.

The Women's Medical Association of New York City desires to pay a permanent tribute to Dr. Mary Putnam Jacobi. In selecting a form of memorial the association felt it should be something that furthered the present urgent needs of women in medicine, thus perpetuating the spirit of Dr. Mary Putnam Jacobi's career. To this end it has been decided to establish a fellowship in her name to give greater opportunity to women for graduate study in medicine.

The sum of $8,000 has already been raised by prominent persons throughout the country interested in the establishment of this fellowship. Mrs. Russell Sage was the donor of $1,000, and other contributions have ranged from $500 to $2.

Dr. Putnam Jacobi won an international recognition and reputation as a woman physician in Paris, and opened the Ecole de Médecine to women. She was the first woman admitted to the New York Academy of Medicine, and her remarkable hospital work and medical writings placed her at once with the leading medical lights in the nineteenth century. An early member of the League for Political Education of Woman, the Equal Suffrage Association, and the Consumer's League, she accomplished a noble work for women.

The Fellowship Fund must amount to at least $25,000 in order to provide an annual income of $1,000, and render efficient aid to post-graduate women students in medicine. The Women's Medical Association of New York City (Treasurer, Eleanor Tomes, M.D., 136 East 30th Street) invites the hearty and generous co-operation of all who desire to further the higher education of medical women of the United States. Among those interested in this Memorial, whose names are on the list of honorary members of the committee, are: Prof. Felix Adler, Mr. Jacob A. Riis, William Osler, M.D., Pres. Nicholas Murray Butler, Hon. Seth Low, Pres. Benjamin Ide Wheeler, Mrs. Henry Villard, Pres. M. Cary Thomas, Mr. Richard Watson Gilder, Dean Laura Drake Gill, Rev. Percy Stickney Grant, Pres. J. Y. Schurman, Miss Grace H. Dodge, Charles L. Dana, M.D., Howard A. Kelly, M.D., Mrs. Ellen H. Richards, Emily Blackwell, M.D., Francis P. Kinnicutt, M.D., Mrs. Frederick Nathan. Members of the working committee are: Chairman, Annie S. Daniel, M.D., 321 East 15th Street, New York City; Treas., Eleanor Tomes, M.D., 136 East 30th Street, New York. Auditors, Gordon Macdonald, Josephine Ettlinger, LL.M.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING SEPT. 28, 1907.

E. C. TAYLOR, passed assistant surgeon. Ordered to the Naval Hospital, N. Y.

F. W. S. DEAN, passed assistant surgeon. Detached from the Navy Yard, New York, N. Y., and ordered to the "Alabama."

W. A. ANGWIN, assistant surgeon. Detached from the "Scorpion," and ordered to the Naval Hospital, Norfolk, Va.

J. G. FIELD, surgeon. Detached from duty with Marine Rendezvous, Houston, Texas, ordered home, and granted leave for 6 weeks.

H. W. COLE, assistant surgeon. Detached from the "Alabama," and ordered to the Naval Training Station, Newport, R. I.

H. A. MAY, assistant surgeon. Ordered to the Naval Hospital, Norfolk, Va.

The following officers detached from duty at the places indicated after their respective names, and ordered to instruction at the Naval Medical School, Washington, D. C.: Assistant Surgeons, H. A. GARRISON, Naval Hospital, Newport, R. I., R. HAYDEN, Naval Hospital, Annapolis, Md., S. L. HIGGINS, Naval Hospital, Norfolk, Va., F. W. SMITH, Naval Hospital, New York, N. Y., O. V. HUFFMAN, Naval Hospital, Norfolk, Va., G. TRIMBLE, Naval Hospital, Norfolk, Va., H. R. HERMESCH, Naval Hospital, New York, N. Y., Acting Assistant Surgeons, F. W. MCGUIRE, F. W. P. HOUGH, Naval Hospital, Boston, Mass., and K. C. MELHORN, Naval Hospital, Norfolk, Va., Assistant Surgeons, E. V. VALZ and J. C. CLAYTON, ordered to the Naval Medical School, Washington, D. C.

Surgeon J. S. TAYLOR, commissioned surgeon from Oct. 7, 1906.

Surgeon K. OHNESORG, commissioned surgeon from June 16, 1907.

Passed Assistant Surgeon B. H. DORSEY, commissioned passed assistant surgeon from March 2, 1907.

Passed Assistant Surgeon, C. T. GRAYSON, N. T. MCLEAN, commissioned passed assistant surgeons from June 28, 1907.

Assistant surgeons C. W. O. BUNKER, H. F. LAWRENCE, C. J. HOLEMAN, G. D. HALE, A. B. HAWARD, appointed assistant surgeons from Sept. 21, 1907.

SOCIETY NOTICES.

CENTRE DISTRICT AND MERRIMACK COUNTY MEDICAL SOCIETY.—The Quarterly Meeting, being the one hundredth anniversary of the society, will be held Tuesday, Oct. 8, 1907, in the Senate Chamber, State House, Concord, N. H.

NEW YORK AND NEW ENGLAND ASSOCIATION OF RAILWAY SURGEONS.—The seventeenth annual meeting of the association will be held at the Academy of Medicine, New York City, Nov. 14, 15, 1907, under presidency of Dr. T. H. Dana, of Cortland, N. Y.

Dr. Robt. Dawbarn will deliver the "Address on Surgery" on Nov. 14, and on the following day will give a clinic demonstrating his method of sequestration.

EIGHTH ANNUAL MEETING OF THE NATIONAL ASSOCIATION FOR THE STUDY OF EPILEPSY.—The eighth annual meeting of the National Association for the Study of Epilepsy will be held at the Jefferson Hotel, Richmond, Va., Oct. 24, 25, next. Addresses will be given at the first session by the Governor of Virginia, the Mayor of Richmond and the President of the Medical Association of the State of Virginia. Responses to these addresses will be made by Dr. Everett Flood, President of the association, and Dr. William P. Spratling, of the Craig Colony for Epileptics, Sonyea, N. Y. Reports from all states in this country which are now caring for epileptics will be made by the secretary.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.—The fall meeting will be held in Sprague Hall, Medical Library, Boston, on Wednesday, Oct. 2, 1907, at one o'clock.—Business: What action, if any, shall this society take in the matter of reform in medical expert testimony? Scientific Papers; a symposium on sudden death.—1. Sudden death in a synopsis of twenty years of medico-legal work, by Dr. Francis J. Canedy, of Shelburne Falls, president of the society. 2. Sudden death from cerebro-spinal lesions, by Dr. George P. Twitchell, of Greenfield. 3. A case of justifiable homicide, by Dr. Silas D. Presbrey, of Taunton. 4. A case of sudden death resulting from abortion, by Dr. Oliver H. Howe, of Cohasset, and Dr. William F. Whitney, of Boston. A large attendance is especially desired at this first meeting of the year.

OLIVER H. HOWE,
Recording Secretary.

RECENT DEATHS.

JOHN HOWARD THURLOW, M. D., M.M.S.S., died in Roxbury, Sept. 29, 1907, aged fifty-four years.

DR. PANTALEON CANDIDUS, long a practitioner in the Williamsburg District of Brooklyn, N. Y., died on Sept. 25, in the seventy-sixth year of his age. He was born in Germany and was graduated from the College of Physicians and Surgeons, New York, in 1872. Dr. Candidus was prominent in Masonic circles.

VIVIAN DANIEL, M.D., M.M.S.S., of Watertown, died Sept. 24, 1907, aged forty-one years. Dr. Daniel was born in Cornwall, England, Nov. 26, 1865. His parents went to Canada while he was still an infant, and later moved to East Boston, where he attended school. He was graduated from the Harvard Medical School and from the Boston City Hospital, beginning practice in Watertown in 1897, where he built up a large practice. He had been a member of the Waltham Hospital Staff since 1898, town physician and a member and chairman of the Watertown Board of Health. Dr. Daniel was married in 1904 and his wife survives him. He died at the Waltham Hospital after an illness of two weeks of appendicitis.

DR. PETER M. WISE, of New York, who had been a sufferer from locomotor ataxia for several years, died in the J. Hood Wright Memorial Hospital on Sept. 22, from an overdose of a prescription, said to be composed of morphine, hydrated chloral and sodium bromide, which he had been taking for the relief of pain. He was found in his bed room by his wife in an unconscious state, and removed to the hospital, where it was found impossible to revive him. Dr. Wise was fifty-six years of age and a native of Batavia, Genesee County, N. Y., and was graduated from the medical department of the University of Buffalo in 1872.

BOOKS AND PAMPHLETS RECEIVED.

Report of the Surgeon-General of the Army to the Secretary of War. For the Fiscal Year ending June 30, 1907. Washington. 1907.

Heart Disease and Blood Pressure. A Practical Consideration of Theory and Treatment. By Louis Faugeres Bishop, A.M., M.D. Second edition. New York: E. B. Treat & Co. 1907.

What should be the Attitude of the Profession toward the Hygiene of School Life? By Richard Cole Newton, M.D. Reprint.

Zeitschrift für den deutschen Unterricht. Von Prof. Dr. Otto Lyon. Leipzig and Berlin: B. G. Teubner. 1907.

Original Articles.

THE NEED OF POPULAR LECTURES ON INSANITY.*

BY HENRY R. STEDMAN, M.D., BROOKLINE, MASS.

A VERY limited experience, it is safe to say, is enough to satisfy any alienist that far less is known and that more mistaken notions prevail about insanity and the insane among people generally than is the case in any other department of medicine.

This surprising public ignorance is found among the unthinking and the educated alike, and together with other harmful results has long exposed physicians and their subordinates in hospitals for the insane to misrepresentation and reproach and the relatives and friends of the inmates of these institutions to constant uneasiness and sometimes the greatest anxiety through sensational and false reports regarding their treatment. It is also reasonable to believe that much of this might be averted or greatly modified by the dissemination of accurate information from authoritative sources regarding the disease and the methods employed in treating it, the safeguards against illegal commitment and abuse of patients in hospitals, as well as the comfortable housing, good general care and medical attendance they receive. To be sure, hospital reports might often tell the story if they ever reached the friends of the ordinary patient and were not too full of other matters to appeal to them.

For much of this ignorance there is abundant reason. By the very nature of their disease, the mass of insane patients must of necessity be cared for in hospitals at a distance from home for long periods, where their relatives can see them but seldom. Thus the opportunities for observing the patient and his disease close at hand that obtain in cases of physical disorders, and familiarizing themselves with his true condition and the difficulties of his proper management, aided by the information and advice of the physician, is in most cases, except, perhaps, for a few days, practically impossible. The same reason explains in a measure the unfamiliarity of the general practitioner with insanity and the fact that there is no branch of medicine in regard to which physicians who are not engaged in the practice of it are so ready to admit their ignorance, and no class of cases which they are more anxious to avoid.

The usual avenues of information about the disease thus closed against it, it is natural that the popular belief should be satisfied with the insanity of the newspaper, the periodical and the novel, that people should run after false prophets, and that secrecy and mystery should shroud the disease, begetting false and impossible ideas of its victims and keeping alive the prejudice regarding their treatment which still exists after so many years of progress in the amelioration of their lot.

But it is by no means in this direction alone that the popular ignorance and error regarding insanity manifests itself. There are few aspects of the disease, in fact, which do not call urgently for public enlightenment. How little is generally known of the signs of approaching insanity, for example, and how common an experience it is to see plain indications of the disease disregarded until an overt act, sometimes disastrous, even fatal, has occurred. Of the causes of insanity, also, the precise knowledge of which in individual cases often baffles the alienist himself, not enough is known by the laity to lead it in many cases to take ordinary precautions for its prevention. Mental hygiene also, the study of which is of vital importance to the individual and the race, is only just beginning to raise its head in the vast growth of investigation into and knowledge of the prophylaxis of disease that is becoming so widespread.

The idea of public lectures on insanity is not new. It had its germ in the broad humanitarian and economic measure of patronage or aid societies for the insane which have flourished for more than twenty years in England, France, Germany and Switzerland, a feature of whose work was combating the prejudices existing in regard to mental maladies. In these associations, it will be remembered, originated the system of the after care of the insane, which at last seems to have taken a foothold, and it is to be hoped a firm one in this country. Popular lectures on insanity found a strong advocate in Morel, of Belgium, who addressed our twenty-fifth National Conference of Charities and Correction on Guardian Societies for the Insane, and our appeal cannot be better fortified than by quoting his words in advocacy of this measure as one feature of the work of a guardian or patronage society. "In my opinion," he says, "much good could be done by giving popular addresses upon the predisposing and exciting causes of insanity and preventive treatment of the malady. When once these questions become understood by the public, mutual aid, moral as well as material, becomes possible. From that moment the insane will be considered as sufferers from disease. These popular addresses should instruct as to the patient's early treatment, giving short and clear descriptions showing how a mental trouble can be recognized. People still remain distrustful of hospitals for the insane. They do not believe as they should that many cures are possible and that they are more frequent and rapid if the patient be placed early under treatment. Guardian societies should in this way help to prepare people by information which shall combat these prejudices, and the public should be taught to take an interest in what actually goes on in asylums and how patients are treated there. These results can only be obtained by constant co-operation among persons of broad ideals who shall interest themselves in arranging public lectures in which shall be set forth the suffering engendered by mental disease, the hope that lies in early treatment and the conditions which may contribute to recovery and prevent a recurrence of the disease."

Most of us have long wished that these and

* Read at the meeting of the American Medico-Psychological Association at Washington, D. C., May, 1907.

other truths about insanity might be publicly and plainly brought home to people in this way, and now is the propitious moment for making the effort, when the tide is so strong in the direction of popularizing the knowledge of medicine in its other branches, a tendency originating in the tuberculosis crusade which has assumed such large dimensions and is accomplishing so much toward checking the spread of the disease. Two or three years ago the first step in the medical education of the public was taken by the British Medical Association, and the *British Medical Journal* reports that the popular lectures at its annual meetings have attracted large audiences, encouraging the hope that the plan may later be developed into a fully organized system.

Throughout the winter of 1906–7 a long and comprehensive series of popular lectures embracing a great variety of subjects in medicine and surgery has, for the first time in its history, been given at the Harvard Medical School by its professors and instructors every Saturday and Sunday with surprisingly successful results in point of attendance and general interest. The newspapers have given fairly accurate reports of the lectures and sensible editorial comments have been frequent. This shows that these are live matters with people in general. In this schedule of subjects, psychiatry had no place, but this omission will be remedied next winter when several popular lectures on mental disease will be given as a part of the regular course of popular medical lectures delivered at the Harvard Medical School; and the endeavor toward securing this desirable end in Boston has led us to urge at the same time by this appeal a general movement in the same direction in other parts of the country.

The credit of inaugurating the first series of public lectures on insanity is due to the Psychiatrical Society of New York City. Under its auspices Dr. Adolf Meyer lectured last winter on "Modern Psychiatry, its Possibilities and Opportunities"; Dr. August Hoch on the "Manageable Causes of Insanity"; Dr. C. L. Dana on the "Data of Heredity"; and Dr. Allan McLane Hamilton on the "Development of the Legal Regulations Concerning the Insane." These lectures were intended for the general physician and non-professional leaders of sociological interests as a basis for the organization of a movement toward prophylaxis and the development of sound interest in this eminently important topic. They were of an academic character and, on the whole, less likely to appeal to the general public than other subjects that might be selected, but were quite well attended and will probably be continued in the coming winter.

The ideal arrangement for a course of such lectures should be one, we think, which would attract all classes of hearers. One set, for example, like those just referred to for the more educated, and another, given perhaps in a central locality, which should deal with the more practical aspects of the disease. The auspices under which the popular lecture on insanity should be given are most important. A prominent medical school would seem to be the best indorsement, and if given, as at the Harvard school, as a part of a comprehensive schedule of popular lectures on disease in general, the association of the two would go far toward correcting the prevailing idea that insanity is something apart and not a disease to be classed with other maladies. Boards of insanity also would do well to encourage and institute public lectures, and medical societies of prominence and influence would be sponsors of weight with the community for such addresses. It is very necessary to prepare the ground for such an unusual departure in public instruction by advertising them freely in the press and by sending out a large number of circulars to persons interested in all kinds of eleemosynary work, social reform, schools, hospitals, courts and other institutions.

Appropriate subjects will occur to all. Among those which would seem more especially to appeal to the educated classes are, for example:

1. Hereditary Conditions Influencing Insanity: The intricacy and uncertainty of laws of disease-heredity. The ascertained average proportion of insane relatives to the number of sane persons in a community. The curability of attacks of insanity in patients with strong hereditary taint, etc.

2. Mental Hygiene, in its protean aspects.

3. The Criminal Aspects of Insanity: Crime a common symptom incident to the disease. Pleas of insanity and demonstration by statistics of the actual number of criminals (far smaller than commonly supposed) who escape punishment on that pretext. The many cases which never come into public notice of criminals for whom this plea is made that are found by experts to be *not* insane. The large number of convicts in the penal institutions of all countries who were insane when committed. Tests of responsibility and recommendations for new legislation which shall insure accurate and just expert decisions, etc.

For the public at large the following subjects occur to the writer, and it is in popular exposition of these questions that we probably shall come closer to the main object of such lectures and the real needs of the people in general as regards matters relating to insanity.

1. The True Nature of Insanity: Bad as it is, it is not necessarily so formidable a disease as it appears to be to the minds of people in general. Small proportion of violent "raving" patients. Large numbers of mild cases that never enter a hospital. Comparative frequency of recoveries, temporary and other, and long intervals of health. Short duration of many attacks. Similarity in this respect to general disease. Great advantage of the early treatment of pronounced cases away from home, etc.

2. The Reliable Signs of Approaching Insanity: Possibility of averting an attack. Precautions against dangerous acts. Methods of commitment, etc. The increasing number of voluntary patients in hospitals for the insane. Emergency, cases, etc. The frequency in sane people of minor and transient morbid mental states, fears, etc.,

and even hallucinations that are really unimportant and do not betoken insanity.

3. The Manageable Causes of Insanity.

4. Alcoholism and Insanity.

5. The Care and Treatment of an Insane Patient in a State Hospital from Admission to Discharge. Safeguards against illegal commitment. Supervision of hospitals by state boards of insanity. The large number of discharges (bearing on the popular belief that many are sent to insane asylums, but few come out). Diet of the patients. Systematic training of the nurses. Oversight of nurses and precautions against neglect, abuse and escape of patients. Medical attention to patients and study of the disease in hospitals. Harm done by the usual newspaper accounts of insane patients and hospital management. The contrast between care at home and hospital care. Condition of patients when brought to hospitals and best means of transportation of difficult cases, etc.

With such a list of subjects to draw from, it would seem easy to inaugurate a suitable course of lectures which could hardly fail, if under the right auspices, to enlighten and ease the public mind.

But the manner in which the subject shall be presented to the audience is quite as important as the subject itself. This has been effectively urged in editorials on the subject of popular medical lectures in the Boston Medical and Surgical Journal. A tendency has been noticeable in the lectures thus far given to paint in too somber colors and to make too much of the dangers of incurring this and that dread disease for lack of proper precaution, and for want of care in analyzing statistics, magnifying the prevalence or increase of the disorders. Now while the possibilities of harm should not be understated, neither should they be exaggerated to the extent of creating unnecessary and unhealthy alarm. The utmost care should be exercised to prevent misconceptions on the part of our hearers, theories should be discarded and only actual ascertained facts dealt with which have a definite, practical bearing. The difficulties are in one way far greater than in lecturing to a class of medical students and the temptation greater to speak with less accuracy to a popular audience. It goes without saying that what is said needs to be simply, clearly and graphically put. For the popular medical lecture to be most effective requires in a medical man, according to President Eliot (who originated the course at the Harvard Medical School), the power of interesting description with telling exposition and moving exhortation. To apply these several cautions to psychiatry: the terrors of insanity and its treatment have held the boards far too long, and the more we are able to say with truth that will tend to lessen its horrors in the minds of the community, the better shall we serve the purposes of true psychiatry; and the more widely and generally the nature of our work is known, the more the dignity and importance of our calling is enhanced.

HEREDITY IN DISEASES OF THE NERVOUS SYSTEM WITH ESPECIAL REFERENCE TO HEREDITY IN EPILEPSY.*

BY PHILIP COOMBS KNAPP, A.M., M.D.,

Clinical Instructor in Diseases of the Nervous System, Harvard Medical School; Physician for Diseases of the Nervous System, Boston City Hospital.

A belief in the heredity of many diseases, especially those of the nervous system, is one of the accepted tenets of medicine,—a tenet to which every one is tempted to subscribe, whether he notes the invasion of Friedreich's ataxia, Huntington's chorea, or muscular dystrophy, in member after member of some doomed family, or studies the social degradation of the Jukes [1] family, or the degeneration and extinction of the Spanish Hapsburgs.[2] It is a belief, too, which has been held even more strongly by the laity, from the days of the Hebrew prophets until the present time. With the development of the doctrine of the neuropathic or psychopathic predisposition by Griesinger the possibilities of morbid heredity in diseases of the nervous system became multiplied, and the studies of the French writers in particular, Dejerine,[3] Féré,[4] Le Gendre [5] and Paul Raymond,[6] have sought to establish heredity as the dominating etiological factor in the vast majority of nervous and mental diseases.

The whole doctrine of heredity, however, has been modified by the theories of Weismann,[7] which have been accepted by many biologists and a number of physicians. According to Weismann, as is well known, acquired characteristics are not transmitted to the descendant, but any influence which, developing in the lifetime of the individual from some external cause, injuriously attacks the germ plasma, may give rise to some defect or modification in the descendant. Weismann holds that there is a continuous transmission of the germ plasma which contains all the elements of the future being. The ovum, in dividing, transmits an integral part of itself to the new cells, so that the ovum of one generation comes directly from the ovum of the preceding generation, and the personal influence of the generator will have no effect upon the quality of the germ plasma, unless the germ plasma be injured by some external influence, such as trauma or poison. Binswanger [8] affirms that we can speak positively of an inherited morbid predisposition coming from the ancestry, only when germ plasma, pathologically altered in one or both individuals at the moment of procreation, has served to form the new individual. This pathological change in the germ plasma in the generators may be directly inherited from their parents or acquired during their own lives from various injurious causes, such as chronic intoxication (alcohol, morphine, lead), infection (syphilis, tuberculosis), constitutional disease (anemia, leukemia, chlorosis, diabetes, gout, arthritis deformans), or local diseases of the generative tract. This pathological alteration of the plasma leads to a general constitutional weakness of the individual, in whom later

*Read at the meeting of the American Neurological Association at Washington, May 8, 1907.

certain special factors may determine that the nervous system shall first or chiefly give evidence of that weakness.

Although Weismann's theories are not yet universally accepted, Le Gendre and Hähnle,[9] among others admitting that acquired characteristics may be inherited, and although Weismann himself has modified them somewhat, so as to admit certain possibilities of the transmission of seemingly acquired characteristics, or that acquired traits due to an external cause may act on a predisposition, the doctrine, as stated above, is of much importance in our conception of the part played by heredity in the etiology of disease.

Another feature in the manifestation of heredity has been pointed out by Galton,[10] and has been further emphasized by the teachings of Bouchard.[11] In various studies Galton has shown that, although certain characteristics are so common in certain families as to suggest hereditary influence, these peculiarities have a tendency to disappear in a few generations. He has formulated the law, too, that each parent contributes about one half to the make-up of the individual, each grandparent about one fourth, and each great-grandparent an eighth or less. Thus the sound parent may do something to correct the tare coming from the diseased parent.

Galton's ratios, however, are not always constant. Occasionally some ancestor seems to show a remarkable power of impressing his characteristics upon successive generations, as Ernest the Iron of Carinthia impressed the Hapsburg lip and the prognathous jaw upon several hundred descendants through eighteen generations,[12] or as Justin Morgan impressed the peculiar characteristics of the Morgan horse upon an uncounted progeny. The comparative study [13] of the Jukes and the Edwards family points to a similar power. Although some of this remarkable transmission may be accounted for by in-and-in breeding, yet there is much left unaccounted for which opposes Galton's ratios.

The theories of Mendel,[14] long forgotten and recently revived by De Vries,[15] Bateson [16] and others, explain this condition by the dominance of certain characters in heterozygous or impure individuals. According to Mendel, when two individuals possessing opposite characteristics come together, we may regard the germ cells as units. Each cell may contain one or the other of the two characteristics, but not both. These germ cells come together in pairs to constitute the body cells, and these body cells may be pure or homozygous, when both germ cells contain the same characteristic; or impure, or heterozygous, when each germ cell contains a different characteristic. If a given characteristic be dominant in the impure cell, this cell, although composed of two different germs, may resemble the pure cell composed of two similar germ cells. Mendel's theory, moreover, teaches that these impure individuals may give rise to pure types having the dominant characteristic, and that these pure types subsequently give rise to other pure types without variation, — in other words, that the special morbid characteristic of a race has a tendency to become fixed or to disappear, and in either event be reproduced subsequently without a change. According to his teachings, if an individual escapes the morbid defect of his faimly, he is likely to produce offspring without this defect, and thus Mendel finds little room for atavism.

The application of Mendel's theory to human heredity has hardly begun, and the complexity of the problem is so great that it is a question whether its practical bearings can be determined for many years to come. At all events, as Bateson has shown, the facts of heredity must be collected with far greater accuracy than has thus far been done. Bateson points out that data must be presented for each family separately, that the normal members must also be regarded, and that we must be assured that the cases are similar, that is, dependent on one pathological state. It requires but a glance at any collected body of statistics of heredity of nervous disease to show that these requisites have almost invariably been disregarded.

Recalling the various theories of Weismann and Mendel, if we turn to the recorded data of morbid heredity we find these data absolutely unsatisfactory, if not utterly worthless. The whole teaching as to the etiological importance of heredity rests upon a mass of inaccurate, undigested data which often have no bearing at all upon the real etiology of the disease under consideration.

In the ordinary discussions of nervous heredity we speak of similar and dissimilar heredity, — the latter manifesting itself as the neuro-psychopathic predisposition. Similar heredity is far less frequent than neuropathic heredity, and is seen most strikingly in certain rare diseases, — Friedreich's ataxia, Huntington's chorea, muscular dystrophy and the like. Occasionally it is noted in some of the more common diseases, especially in migraine, as is shown by a recent case under my observation, where migraine existed in eight out of sixteen members of a family in three generations. The fact that these rare diseases occur with remarkable frequency in the members of one family seems a striking demonstration of their hereditary character, especially when the occurrence of the disease is noted in generation after generation, with fatal regularity.

Nevertheless, this is not absolute proof that the disease is due to heredity. On the day that I write these words I have chanced to see two cases of Friedreich's ataxia. In one, a son of intelligent parents, no other case was known in the family. In the other no case was known in the antecedents, although two other cases had occurred in the same generation, in a sister and a cousin. The old theory of atavism, that a morbid tendency may be latent for several generations and then reappear, was formerly invoked to explain these cases where no traits of the disease could be found in parents, grandparents or collaterals of either generation, and this explanation could usually not be contradicted, because few of us know anything definite about our great-grandparents and remoter

ancestry. Even in the case of Queen Victoria nothing whatever is known of at least one of her great-grandparents.[17] This explanation, always somewhat hypothetical, can hardly be maintained to-day in face of the teaching of Mendel, that the impure types become unvarying after a generation or two. It occasionally happens, moreover, that we have the opportunity to note one of these rare diseases, apparently of sporadic origin, where no previous case can be discovered in a family, and later we observe its reappearance in a subsequent generation. I had under my care, some twenty years ago, a boy with muscular dystrophy, where no case could be discovered in the antecedents and no definite cause could be made out. Years later, another case of the disease manifested itself in his sister's child.

As I have just said, the occurrence in one family of a dozen or fifteen cases of a disease so rare that only a few hundred are recorded in medical literature, would seem conclusive proof of a hereditary influence at the least, and so much may be admitted. When once the disease is established, it is easy to conceive that the pathological state of the germ plasma may persist in individual after individual among the descendants. Yet these things are little help in understanding the genesis of the affection in individuals where no previous case has occurred in the antecedents. In these cases, too, we find nothing more than ordinary occurrences which might conceivably injure the germ plasma, occurrences which affect the majority of the race at some period or other, trivial accidents, common infections and the like. Even if we assume that such occurrences lead to pathological changes in the germ plasma which are transmitted to the descendants, giving rise to some abiotrophy, why is it that this banal accident so affects the germ plasma as always to cause an abiotrophy of a special set of nerve fibers, — certain ascending tracts in the cord, certain cortical cells, or some of the fibres of certain special groups of muscles?

De Vries' theory that the normal way in which new varieties are produced is by sudden mutation is perhaps a more satisfactory method of explaining the sporadic manifestation of these rare affections. De Vries has found that new varieties appear suddenly and are often constant from the first. He furthermore admits the possibility of a reproduction of the same mutation at different times and in different localities. Yet even if we assume that what is demonstrated as occurring in plant life is equally applicable to man, we find certain effects in the incidence of these diseases which are still inexplicable, such as the predominant occurrence in one sex and transmission by the other, or the disappearance of the disease in certain branches, and its persistence in others, although the tainted stock be crossed with new blood to the same extent in either case.

Although the origin of these rare diseases is still obscure, nevertheless it is possible that they may arise by sudden mutation and persist in the affected family by true heredity, owing to the change set up by this mutation in the germ plasma. It is incorrect, however, to regard heredity as the cause, and the tendency to recurrence of the disease in the affected family steadily diminishes by crossing with healthy individuals, as is shown by the teachings of Galton and Mendel. In this process of regeneration, however, although the affected stock may gradually be restored by cross-fertilization, a certain number of diseased individuals may be produced during one or more generations, until the morbid taint is obliterated, so that the old warning against breeding from such a stock is justified.

Turning now from these rare diseases in which the family occurrence is so great as to compel the belief that heredity plays a considerable part in their transmission, if not in their origin, we must next consider the part played by heredity in the production of the more common diseases of the nervous system. In these affections it is generally admitted that similar heredity is rare, and almost all writers agree in laying chief stress upon the neuropathic or psychopathic predisposition. In this predisposition are included all the different forms of insanity, all the functional and organic diseases of the nervous system, all peculiarities of mind and conduct, genius, the artistic temperament, criminality, alcoholism, pauperism, and even tuberculosis, cancer, diabetes and the different affections classed under arthritism.

The most available statistics for the study of the influence of this neuropathic heredity are those referring to the heredity of insanity; but these are useless for any study except that of the futility of human effort, since the vast amount of labor employed in their collection is wasted, on account of the habit of regarding insanity as one disease, and mixing the statistics of general paralysis, senile dementia, paranoia and all other forms of mental disease included in the various classifications together into one grand whole, and then drawing conclusions as to etiology, symptomatology, prognosis, prophylaxis and treatment, — a method as scientifically accurate as it would be to draw similar conclusions from a collection of cases of bronchitis, pleurisy, pneumonia, pulmonary tuberculosis, pulmonary cancer and embolic infarction of the lung, or, as Von Jauregg [18] suggests, to draw similar conclusions in regard to skin diseases from lumping together scarlet fever, favus, eczema, herpes zoster and psoriasis. I have therefore studied the statistics of the heredity of epilepsy, often regarded as the most hereditary of all nervous diseases,[19] in 320 patients of my own and in 1,200 patients at the Massachusetts Hospital for Epileptics, the data of which were put at my disposal by the kindness of Dr. Flood, and have compared them with the statistics cited by different authors. Even here the error which Bateson condemns, and all writers on insanity have fallen into, is not wholly avoided, since epilepsy must be regarded not as a single disease, but as a syndrome due to various affections of the brain. The error, however, is not quite so glaring as in the collections of statistics of "insanity."

The method which obtains in the collection of statistics as to neuropathic heredity in epilepsy and other nervous diseases seems to be as follows: a more or less careful inquiry is made as to the existence of any form of nervous or mental disease, and often the other diseases referred to above, not only in the direct ascendants, but also in the collaterals. Cousins are often included, as by Turner,[20] forgetful that we usually have there the introduction of a different stock. If any such disease is found, the case is regarded as manifesting neuropathic heredity, either similar or dissimilar; the total number of cases in the ascendants and collaterals is usually disregarded. If the heredity be dissimilar, as is usually the case, little or no attention is paid to the form or nature of the nervous affection occurring in the other members of the family. The percentage of cases showing neuropathic heredity thus ascertained is calculated. This percentage is apt to be larger than the percentage of any other one alleged cause, and the conclusion is drawn that neuropathic heredity is the chief determining factor in the production of epilepsy or any other form of nervous disease under consideration.

I have put down in the accompanying table the figures given by different writers and the percentage of neuropathic and similar heredity in epilepsy as found by them. This percentage varies from 11% in the old statistics of Delasiauve or 14½% in the statistics of the Massachusetts Hospital for Epileptics, to 87% claimed by Kraepelin; and the percentage of similar heredity varies from 1% as given by Osler to 37.2% as given by Turner. The discrepancies are so great as not to be readily explained, and they leave us in doubt as to the real prevalence of neuropathic heredity among epileptics. The same discrepancies occur in other statistics as to heredity in nervous disease. In Munich different men in the same asylum for the insane found in different years from 37% to 66% of morbid heredity. Krauss[21] finds that the percentages in the different asylums of New York State vary from 14% to 76%. Hähnle has collected equally discrepant statements concerning morbid heredity in special forms of mental disease, and Binswanger[22] quotes like variations in the statistics as to the heredity of hysteria.

It is undoubtedly true that the more exhaustive the inquiry and the more intelligent the patient or his family, the more information will be elicited and the greater will be the percentage of morbid heredity discovered; but I must confess to a certain degree of doubt as to whether this is a sufficient explanation of the variation shown in these percentages. At the Massachusetts Hospital for Epileptics, for example, the inquiry I think has been more minute and careful than in my own cases, and yet the percentage is less than one half of the percentage I have found and less than one third of that found in New York.

The etiological relation of syphilis to tabes has been established statistically by the discovery that whereas syphilis exists in about 10% of non-tabid patients, it exists in about 90% of tabid patients. This points to the fallacy of the conclusions drawn from the statistics as to morbid heredity in epilepsy and other nervous diseases. The percentage of neuropathic heredity in the healthy has been absolutely ignored, and it is only within recent years, and in a single community, that any extensive inquiry as to such heredity has been made, — in Zurich by Thomann-Koller[23] in 1895, and by Diem[24] in 1905. Naecke[25] and Jost[26] have made researches on a much smaller number of individuals, which seem far less thorough. Thomann-Koller found neuropathic heredity in 59% of 370 healthy persons, and Diem found such heredity in 66.9% of 1,193 healthy persons. In 370 insane, Thomann-Koller found 77% of morbid heredity, and Diem found the same percentage in 3,515 insane. They both conclude that the difference between the morbid heredity of the sane and the insane is so slight as to be disregarded, but they have both found that,

on limiting the inquiry to the morbid heredity in parents alone, and to the prevalence of mental disease only, excluding many of the forms of organic nervous disease, such as apoplexy, there is a greater amount of morbid heredity among the insane.

Another fallacy of this method of estimating morbid heredity is that little attention is paid to the nature or etiology of the forms of disease existing in the patient's family. Dejerine gives a family tree which he regards as one of the most conclusive in its indication of nervous heredity, and he counts in, as showing the neuropathic taint, deformity, deaf-mutism, idiocy, and exophthalmic goiter, as well as various forms of mental and nervous disease. It is so obvious that a case of nervous or mental disease of traumatic, infectious or toxic origin should not be considered as showing a special neuropathic taint, that it would seem impertinent to mention it, were it not so invariably ignored. The existence of several cases of epilepsy in the children of one family, even, cannot be regarded as proof of an inherited tendency, unless we know that they are not due to injury at birth from too small a pelvis.

The data at our disposal for determining the importance of heredity in the production of epilepsy, and of other forms of nervous and mental disease, are therefore inadequate, so far as they relate to a general neuropathic predisposition, since there is no proof that there are more neuropathic conditions in epileptics, for example, than in healthy persons, and the cases of nervous or mental disease that do occur may be due to causes affecting the individual alone, and not to morbid changes in the germ plasma. One thing alone points to the possibility of an hereditary influence in epilepsy. Turner [27] assumes that there are from one to three epileptics to every thousand persons. In the figures furnished me by Dr. Flood, in 1,200 cases of epilepsy there was a similar heredity in 29 parents. The exact number of parents is unknown, but estimating them at the maximum of 2,400, this would give over 12 cases of epilepsy in a thousand parents, which shows that there is a somewhat larger percentage of epilepsy than the average in the direct ascendants of the epileptic. Other statistics would, of course, increase this percentage. We see, therefore, that the data as to morbid heredity in the production of epilepsy are too misleading to warrant any definite conclusions, and the skepticism which has been expressed by various writers, from Delasiauve to Marie,[28] Sachs, Osler, and Von Jauregg has a reasonable foundation. We must not forget the old adage of Morgagni, — *Observationes perpendendæ non numerandæ sunt.* Each case must be considered on its own merits, and dissimilar affections must not be compared. We must be sure that a case is idiopathic epilepsy, and not epilepsy symptomatic of brain injury or cerebral infantile paralysis. We must study the whole life history of all the other members of the family previous to the generation of the patient, to determine the general physical health of the ascendants, and to eliminate the various accidents of pregnancy and childbirth. If nervous disease occurs in the family, we must consider its nature and character, whether indicative of an intrinsic nervous defect, or the result of some extrinsic cause, such as infection or trauma. Furthermore, we must study the patient's own life history, and decide how great an influence post-natal causes play. A child of thoroughly neurotic parents may owe much of his nervous disorder to faulty example, lack of proper restraint, defective training, late hours and improper feeding, and little to his direct inheritance. Only by such thorough study can we come to any definite knowledge of the prenatal causes of disease. If we continue to note "cousin had chorea," "uncle apoplectic," "brother paralyzed" (fractured spine), "aunt insane" (puerperal), and then decide that the patient has hereditary disease because such antecedents are found in 40% of the cases, although they exist in 60% of healthy persons, our conclusions will remain wholly unworthy of consideration.

In studying the etiology of epilepsy, the following case will show the importance of certain prenatal influences. Three older brothers in a family were strong and well. The youngest, always a delicate child, became epileptic. The grandparents on both sides showed no special indications of disease. The parents were healthy until the close of their lives, but they died two years after the birth of this patient, the one of cancer and the other of tuberculosis. No history of nervous disease or epilepsy existed in the family, but is there any question that the diseases which affected the parents led to a defect in the germ plasma and the production of a weaker child in whom epilepsy might develop? Such I believe to be the true interpretation of much of the so-called neuropathic predisposition. Some morbid process, constitutional disease, chronic intoxication, infection or local injury to the generative tract causes pathological changes in the germ plasma, and these changes give rise to a general constitutional weakness in the progeny. The child is not simply a neuropath or a psychopath, — he is a weakling. The constitutional weakness shows itself, as we often see, in the various stigmata of defective development and in general physical weakness, — a weak digestion, a small thorax, a hypoplastic aorta, deficient circulation, poor teeth, slender frame, delicate muscles, undeveloped sexual organs, a small spinal cord and the like. Given this constitutional weakness as a consequence of pathological changes in the germ plasma, various forms of nervous weakness may develop from extrinsic causes which determine whether the weakness shall be manifested in the nervous system, and if so, in what particular way it shall appear. In this way, too, acute infections may temporarily injure the germ plasma, so that the offspring conceived or in utero during the acute infection may show marked neurotic phenomena, while offspring conceived before and after the period of infection may be healthy, and the parents themselves may be for the rest of their lives in perfect

health. This explains the alleged preponderance of nervous defects in the children of alcoholic subjects, or the French "children of the siege." Unless, however, there be some general or local cause of injury to the germ plasma, it is doubtful whether any acquired mental or nervous disease of the ancestors can be the starting point of a pathologically tainted family, or even of sporadic cases of disease in the descendants (Binswanger, Forel [29]).

It is apparent, therefore, that the old data upon which the present doctrine of neuropathic heredity is based are misleading, and a much more thorough investigation of the whole question is required before we can draw trustworthy conclusions. Each individual case must be studied by itself, with due regard to the frequency of disease in the ascendants, especially in the direct line. Such disease in the collaterals seems to be of slight importance. The nature of each case must be carefully considered, especially with reference to possible injury to the germ plasma. The frequency of disease in the ascendants needs to be compared with the frequency of disease in the ascendants of healthy persons, and finally all possible causes of disease in the individual himself must be considered, and special attention must be paid to the whole life history of the patient, to determine how far a defective organization is at fault, and how far other influences, such as accidents of parturition, faulty training, bad examples, injuries, infections and intoxications have led to the development of the disease. Only by such study can we determine accurately the influence that heredity exerts.

At the present day there is an increasing dread among the laity of heredity in general, and neuropathic heredity in particular. This dread exerts a considerable influence upon marriage and the procreation of children, and threatens to give rise to ill-considered legislation. The present doctrines are certainly too pessimistic. Galton has pointed out the tendency to regeneration, or to return to the normal average in a generation or two, and further study may throw light upon the question raised by Mendel, as to whether morbid traits may be dominant or recessive. Weismann's teachings show us the importance of guarding against all injuries which may affect the germ plasma, so that it may be possible to guard against the procreation of weaklings, either with or without a history of long continued disease in the ancestry. Furthermore, investigation will often permit us to reassure the individual, when some case of nervous or mental disease develops in another member of the family, or even in himself, and to explain to him that it may indicate no disposition to similar disease in himself or his descendants.

HENRIK KELLGREN AND HIS METHODS OF MANUAL TREATMENT.

BY EDGAR F. CYRIAX, M.D., LONDON, ENGLAND.

ALTHOUGH it may truly be said that the name of Henrik Kellgren is known almost throughout the civilized world, yet it must be conceded that few persons know anything definite about the man or the methods of treatment he employs. The following brief sketch of his life and work is intended to supply the particulars hitherto lacking.

Henrik Kellgren, born in 1837, at Alingsas in South Sweden, matriculated in 1855, and in 1858 became an officer in the Swedish army. From 1863 to 1865, he went through the course of training at the Royal Gymnastic Central Institute in Stockholm, and in the latter year received the diploma, whereupon he accepted a post as teacher of pedagogical gymnastics in Lidköping. It was in the latter place that he obtained his first case for treatment by medical gymnastics, and already at this early period he realized how important it is to give not merely local, but also general, treatment (of this more hereafter), but owing to his preoccupation with military duties, he was not yet led to develop any great interest in the subject of medical gymnastics as a whole.

At this time a series of troubles fell upon him, and the death of his wife and only son changed the course of his life. Leaving his native land, he went to Germany with the intention of proceeding to Algiers, where the French were then in conflict with the insurgent Arabs. At Bremen, he became acquainted with a medical gymnast, Dr. Ulrich, with whom he stayed for some weeks. This Dr. Ulrich was the first to recognize in young Kellgren, the great natural aptitude for medical gymnastics, which afterwards developed so remarkably; and he urged him to devote himself to this new career. In the end, Kellgren was prevailed upon, and in the year 1869, he settled in Gotha in Thuringia as medical gymnast.

He naturally began to treat on the lines laid down in the Royal Gymnastic Central Institute, but his real talent, aided by instinct, soon led him to remodel several of the exercises on his own

account. He further perceived how much good could be effected through direct stimulation of the nerves; consequently, he gradually developed a nerve treatment, consisting chiefly of frictions and vibrations, which he used in combination with improved active and passive (inclusive of duplicate) movements; and by these means he has treated with unexampled success a number of chronic cases of which some had been previously regarded as incurable. He has also attacked acute cases with wonderfully favorable results.[1]

Kellgren's fame soon spread abroad, and his practice grew enormously. His methods would, without doubt, have been widely taken up, at this time, by German doctors, but that owing to illness from overwork, Kellgren was obliged to retire from active work, and, when his health broke down, he for various reasons decided to come to London. Here, on his recovery, he established an important institute, and later on founded others also at Norderney (1877), Baden-Baden (1883), and Paris (1884). During the summer of 1886 he went, followed by a number of patients, to Sanna, near Jönköping, in Sweden, where he established a summer sanatorium, — now open all the year round, and where Kellgren himself often passes the greater part of the year.

Thousands of people owe their health to Kellgren, and some still live, who, at one time of their life, were regarded as utterly incurable. To how great an extent his successes have contributed to make medical gymnastics known and valued throughout the world is incalculable.

Although Kellgren's treatment has existed for more than thirty-five years, the literature relating to it has hitherto been scanty. Apart from a few newspaper articles which often contained erroneous accounts of Kellgren and his practice, Dr. Arvid Kellgren's work, "Vorträge über Massage" ("Lectures on Message," 1888), was the first to contain descriptions of some of his brother's exercises. In 1890, this book was translated into English, being amplified with descriptions of several more cases treated successfully by the Kellgren methods.

This was for some years followed by nothing of any importance, and, in consequence, I was led to publish my book entitled, "The Elements of Kellgren's Manual Treatment," which claims to be the first attempt at a systematic and scientific description of the subject.

It is probably due to the paucity of information obtainable as to Kellgren's methods that so many errors are prevalent with respect to them. Thus, some authors have been under the impression that the treatment consists wholly of vibrations, while others have believed that there is in it nothing more than hypnotism; since both these ideas are contrary to fact, it is obvious that those who held them had a most inadequate knowledge of the subject under review. The Kellgren treatment is based (a point I desire particularly to emphasize) on a scientific foundation, physiological and anatomical; and it is to be hoped that the profession may soon convince themselves of its true value.

In the following pages, I have aimed at describing the difference between the methods of Kellgren and those of Ling, or rather at indicating the progress achieved by the former beyond the latter.

Unfortunately, at the present time, both in Sweden and elsewhere, the handbook of Wide is regarded as authoritative on the subject of Ling's methods as practiced to-day; I say unfortunately, for it describes them in a form which, compared with earlier practice, shows distinct retrogression.

Most of the following descriptions are contained in my book; but, as the latter has only recently appeared and is not as yet widely known, such repetition as I have indulged in will not be superfluous.

I. Kellgren assigns particular value to the mechanical treatment of the nerves. This was formerly regarded as of very slight importance, P. H. Ling alone using a form of nerve pressure.[2] Branting (1844) brought forward as a novelty pressure of the phrenic nerve and lumbar nerves, and also (1846) of the spinal accessory and the sacral nerves. Somewhat later, nerve pressure, either with or without simultaneous vibrations, came more into use, but apparently without achieving any important results. The enthusiastic Neumann said in 1852: "This is a part of Ling's doctrine which his pupils have least worked out, although they and Branting are well aware that it is of the greatest importance; but its development is proportionately difficult, because the physiological ground work has so far been investigated only very insufficiently, and in part not at all." But in 1856, only four years later, he revised his verdict, saying: "I for my part consider now that these forms of movement can very well be dispensed with, as they can entirely and very advantageously be replaced by duplicate concentric movements." In the handbook of Hartelius (1870) pressure of the arm and leg nerves only is described, and but twenty lines are devoted to this subject in a volume of some three hundred and fifty pages. It should be added that here and there a few other nerves are specified as being suitable for similar treatment.

A few of the different forms of nerve friction and vibrations were described by Arvid Kellgren, and since then have been used by medical gymnasts, but without any acknowledgment of their source. In my book, I have described Kellgren's forms of nerve treatment in considerably greater detail.

The great merit of Kellgren has been his correct development of the processes referred to; in particular, he discovered that the main point of importance was not the pressure, but the mechanical movement set up in shaking the nerves through friction and vibration. And it was he who introduced manipulations following the course of the

[1] See Wretlind and Glatter, "Bref från Dr. Wretlind," Hygeia, Stockholm, Nov., 1872.— Feb., 1873. Allgemeine Betrachtungen über den werth der Heilgymnastik." Wien. Med. Presse, 1875.

[2] We must, of course, take into consideration the great progress made in the physiology of nerves between the eras of Ling and Kellgren; but this does not diminish the value of the modifications and discoveries made by Kellgren.

nerves, which manipulations are called " running nerve frictions and vibrations."

When we consider how everything in the human body is under the influence of the nerves and how many illnesses have their origin, not in the muscles, but in the nerves, it will easily be understood that nothing can be of so great service in these cases as movements of stimulative or sedative effect. Not only the cerebrospinal nerves can be directly treated by Kellgren, but also the sympathetic nerves. Before his time attempts had been made to deal in this way with the solar plexus and the cervical ganglia, but this was of rare occurrence, and in the handbook of Hartelius, for example, the subject is scarcely mentioned. Kellgren, however, discovered that it was possible to deal directly, or indirectly, by reflex action, with almost all sympathetic ganglia through the peripheral nerves that are in connection with them. Thus, for example, all the chest ganglia stand in direct physiological relation to the posterior branches of the dorsal nerves, and can be influenced through the fourth and fifth dorsal nerves on the left side, and the liver through the sixth and seventh on the right side, etc.

The value of all these forms of nerve-treatment can scarcely be over-rated, and it is most remarkable what favorable results can be obtained by them in acute cases; it can, indeed, be safely stated that without them such results would be unobtainable. The same applies to central nervous diseases, *e.g.*, bulbar paralysis, multiple sclerosis, spastic paraplegia, locomotor ataxia, tabes dorsalis, hydrocephalus, etc.

II. For other parts of the body, as well as for the nerves, Kellgren's vibrations and shakings, such as chest shaking and eye vibrations, are of great importance. In all the earlier literature of P. H. Ling, Branting, Rothstein, Roth, Neumann, etc., but a few lines are to be found dealing with such methods, and Hartelius also (1870) refers only briefly to shakings. These movements must consequently up to that time have remained quite undeveloped.

It was Kellgren who succeeded in working out — one might almost say who discovered — this new and splendid method of combating pain and disease. He also discovered the method of executing the vibrations in a manner involving the minimum of fatigue to the operator, so that they could be maintained for much longer periods and, at the same time with greater efficiency. For example, when the fingers are executing a vibration, the muscles in actual use should hardly be felt to contract. Only in a few cases, in which a particularly strong effect is desired, should the muscles of the upper arm or shoulder come into action. Unfortunately, medical gymnasts in general use only this latter method.

These vibrations can be executed either quickly or slowly. The maximum rate is about twelve per second.

Certain quite new forms of shaking and vibration have been developed by Kellgren, such as the following:

(1) So-called "suction-vibrations." The manipulator spreads out his fingers (Fig. 69 in my book) so that they lie on the patient's skin around the spot to be manipulated; they are then set into vibration while the finger joints are slowly flexed, causing the pressure on the skin gradually to increase. Such methods make it possible to treat the thyroid gland in Graves's disease, to accelerate the pointing of an abscess, etc.

(2) " Centrifugal running vibrations." These are running vibrations in a direction contrary to that of venous blood and lymph flow. These manipulations make it possible to treat lymphangitis, erysipelas, and to hinder the upward absorption of toxins.

These two new forms, together with the more ordinary forms of Kellgren's shakings and vibrations, are described in my book in considerable detail.

III. During the last twelve or fifteen years, mechanical vibrators have come largely into favor. The advocates of these " vibrators," " concussors," etc., maintain that the movements are rendered easier of administration, as they obviate exertion on the part of the gymnast, that they may be administered with perfect regularity as long as necessary, and finally that they may also be administered more rapidly. Some " vibrators " execute up to 200 vibrations per second.

That a greater rate than twelve per second should be of any advantage seems to me very doubtful. It must, of course, be conceded that a " vibrator " makes less demand on the manipulator, and its use is comprehensible when we consider that in general the vibrations as administered at present involve strong contraction of the arm and shoulder muscles, demanding great physical exertion, and are consequently only to be maintained for short periods at a sacrifice of sureness and delicacy of touch. As, however, the Kellgren vibrations (as already stated) are produced with a scarcely perceptible contraction of the muscles, the gymnast can execute and maintain them as long and as evenly as may be desired. I have myself never executed such vibrations for more than one hour and three quarters continuously, but I am certain that I could maintain them for a much longer period; the necessity for this, however, could but seldom arise.

The superiority of the Kellgren vibrations lies in the fact that the gymnast preserves the delicacy of his sense of touch, and is thus enabled at will and with great accuracy to vary the vigor, extent and rapidity of the movement, as well as the degree of pressure, whenever the condition of the patient indicates such alteration.

In certain cases characterized by a considerable amount of pain, *e.g.*, acute inflammations of the eye, abdomen and appendix, vibrations produced by machinery are entirely out of the question, as the machine can neither judge by touch nor adjust itself. In consequence of this it has become the practice in certain medico-mechanical institutes in certain cases, as when treating the head or neck, to interpose the gymnast's hand between the vibrator and the part to be manipulated.

Kellgren makes use of many new manipulations, and besides this he has modified already existing exercises. These modifications are difficult to specify exactly, and it is necessary to have technical experience in order to grasp fully the differences from — and advantages over — earlier methods. The following may be specified in particular:

(1) The so-called "Head exercise." Roth and Neumann speak of head-shaking that lasted for some seconds and was combined with passive head-rotation. In time, however, this manipulation fell into disuse and oblivion; the handbook of Hartelius does not mention it. Kellgren reintroduced the head-exercise and developed it further. The following form is used in fever cases:

(*a*) Head-lifting.

(*b*) Vibrations or other manipulations on the head with both hands simultaneously.

(*c*) Nerve frictions or vibrations, local or general.

(*d*) Repetition of head-lifting as conclusion.

(2) Passive movements for the liver, gall-bladder, pancreas, kidneys, spleen, etc., (described in detail in my treatise).

(3) Gymnastic treatment administered during childbirth, as well as during the puerperal state, to combat loss of blood, and as a preventive of puerperal fever.

(4) Modifications of many movements to render possible their use in acute cases; of this, more hereafter.

IV. It is at present the custom to make great use of massage only,—*i.e.*, stroking or kneading,—active movements being greatly neglected. Also vaseline and other fatty substances have come into considerable use in connection with massage; this was in earlier times unknown in the Ling school. Kellgren, on the other hand, assigns small value to such stroking and kneading, nor does he ever use vaseline or similar preparations; his grounds are the following:

(1) With vaseline the movement of the fingers employed in massaging is reduced to a gliding over the skin, the tissues underneath being but little influenced. In the Kellgren method, the fingers of the gymnast remain in contact with the skin, and thus they are enabled to really manipulate the parts beneath.

(2) In consequence of the massage-process the vaseline is rubbed into the opening of the sebaceous and sweat glands, with the result that massage corruptions are often induced, necessitating interruptions in the treatment.

It must further be conceded that, in the long run, massage has a weakening effect on the muscles manipulated. Kellgren administers kneading for only very brief periods at a time, and attaches more importance to duplicate movements, nerve-treatment and vibrations. And Kellgren dispenses entirely with the modern so-called "general massage."

V. In all resisted exercises, and in all passive movements involving movement of joints, Kellgren, where possible, makes use of the so-called "traction"; that is, the gymnast, during the movements, effects a passive stretching of the part manipulated, drawing the distal free end from the proximal fixed one. That in many cases a considerable extra effect is attained by these means will become strikingly clear on performing a movement first without, and then with, traction. This traction has been hitherto only described by Arvid Kellgren and myself.

Without "traction" it would in many cases of partial anchylosis, inflammation of joints, etc., be impossible to make use of any duplicate movements, while, by its aid, it is often possible to induce in paralyzed muscles a slight voluntary movement that would otherwise be unattainable.

VI. In all cases of local disease (except a few of mild character or short duration) Kellgren considers a certain amount of general treatment to be of benefit to the general health of the patient, and this for the following reasons:

(1) In the normal healthy body are contained many toxins and excretory products, which are, however, accompanied by no evil results because the body is able to eliminate them. So soon, however, as it becomes unable to do so, there result states of general or local illness, and the general treatment is of great use in restoring the lost power to eliminate.

(2) A local illness acts as a centre for producing toxins and excretory products, and more work than usual is demanded of the body to get rid of such accumulations. The general treatment facilitates this work.

(3) Toxins and excretory products that are of local origin, and are only treated locally always show a tendency to settle in other weak parts of the patient's system and to give rise to fresh morbid states. The general physical treatment hinders this.

(4) It may happen that only by means of the general treatment can the cause of a particular illness be not only discovered but removed. An inflamed ovary, for example, can, in course of time, through continual irritation of the muscles lying above it, cause a spinal curvature, and it would be an error to deal with the latter (subjective) affected part without, at the same time, administering treatment for the (objective) true source of illness. It would be easy to maintain the proposition above set forth by a long series of examples.

VII. The employment of the Kellgren treatment in acute cases, specific, infectious, or otherwise:

Early attempts of this kind were very few in number;[3] but already during his early years of practice in Gotha, Kellgren had worked out the treatment of acute cases and employed it with magnificent results. As early as 1873 Wretlind recorded several acute cases treated by Kellgren, and in 1875, Glatter spoke in laudatory terms of Kellgren's treatment of pneumonia. Kellgren

[3] "Pneumonia" by Branting (*vide* his farewell address, March 31, 1847), and H. Ling in "Branting's Efterlemnade Skrifter," 1882, p. xxvi; "Acute Pleurisy" by Melicher (*vide* Annual Reports); "Cholera" by Melicher, Becker ("Denkschrift über die Schwedische Heilgymnastik," 1864, p. 64), and others; Whooping Cough by various doctors and gymnasts.

was, in fact, the first to apply manual treatment to a great variety of acute cases that had never before been thus dealt with, and it can safely be said that no other form of treatment has led to such good results. I specify in particular the following illnesses:

Typhus, typhoid, scarlet fever, measles, rheumatic fever, erythema nodosum, erysipelas, acute inflammation of the larynx and pleura, acute tonsilitis, appendicitis, peritonitis, gastritis, enteritis, pericarditis, meningitis, etc.

It is quite impossible in so short a paper to describe the methods used in such cases, and I must restrict myself to referring the reader to the detailed descriptions contained in the following works:

(1) Arvid Kellgren: "Technic of Ling's System of Manual Treatment" (1890), containing eight cases. (In the German edition of this book an additional case is included.)

(2) Möller: "Zur Therapie der Akuten croupösen Pneumonie" (Deutsch. Med. Wochenschr., December, 1900, January, 1901), three cases.

(3) Cyriax: "The Elements of Kellgren's Manual Treatment" (1903); in all thirty-seven cases.

While treating acute cases by manual methods, Kellgren places no restrictions upon diet; he almost always allows the patient to eat what he happens to fancy (especially if the case has been under his care from the commencement), and he has never had any cause to regret his action in this respect. Also Kellgren generally allows the patient to leave his bed on condition that the temperature of the room is suitably warm and that proper precautions are taken against draughts, for it is his opinion that a little movement can only do the patient good. In this connection it must steadily be borne in mind that Kellgren's treatment contributes in a high degree to keeping the digestive organs and nerves in an efficient condition, in consequence of which the strength of the patient is well maintained, and he is enabled to offer considerably greater resistance to the illness. Under this treatment, a patient will scarcely desire to eat what he cannot digest, nor will he desire to leave his bed if not strong enough to do so. On this subject, I must also refer the reader to the experiments of Pawlow, which have shown (although not specifically in the case of fever) that the gastric juice is only secreted when food satisfies the taste. Kellgren is of opinion that to compel a patient to remain in bed against his will can only result in a lowering of his vitality, and, in addition, contribute to establishing a hypostatic congestion, especially of the kidneys, this being a condition to be particularly avoided.

VIII. The old doctrine of the Ling school that the gymnastic treatment is more efficacious, if unmixed with medicine, electricity, etc., has been largely lost sight of. Wide, for example, frequently combines medication with his gymnastics, a combination which can only seem to indicate deficiency on the part of the gymnastic treatment. A natural cure, to be really satisfactory, should not be accompanied by medicine.

This is especially true of central nervous diseases, with regard to which Kellgren has made the following observations: On the one hand, it is very difficult for the Kellgren treatment to effect much progress in cases that have previously been treated more or less unsuccessfully with electricity or strychnine, arsenic, etc.; on the other hand, where such methods have effected some improvement, the latter has been considerably accelerated as soon as the Kellgren method was tried.

It has occurred repeatedly that cases, even of some years' standing, which had never been subjected to electricity or strong medication, were more easily influenced for good, than others which were of more recent origin, but which had undergone such electric or medical treatment. It has also been observed that when certain cases, which had made good progress under the Kellgren treatment, were for some reason removed, in order to undergo a medical or electrical course, the change of treatment was ultimately for the worse.

IX. It often happens now that a doctor who is quite ignorant of medical gymnastics has to superintend a course of such treatment. In such a case, if the patient feels somewhat worse, the gymnastic treatment is often at once suspended, the patient is put to bed and drugs are prescribed, the gymnastic treatment being resumed only when some improvement has taken place. It is clear that, under such circumstances, it is impossible to judge of the efficacy of medical gymnastics.

The Kellgren treatment proceeds on very different lines. Should a patient feel somewhat worse than usual it is often because his illness reaches some small natural crisis. If the treatment is maintained through this period, it will be found subsequently that the patient's condition has materially improved. This improved condition may sometimes continue without any further perceptible modification until another similar crisis supervenes. So long as this condition continues the treatment can be varied as regards frequency, duration and force to suit the patient. When, however, the treatment is temporarily given up during a worse period, the crises are prevented, and as these are the means by which the body tries to get rid of disease, real improvement cannot occur if they are suppressed by enforced rest in bed, diet and drugs.

X. In conclusion, I wish to say a few words about diagnosis by means of palpation. This art, if I may so term it, has been particularly developed by Kellgren. It is very difficult to describe an art of this kind to any one who has not tried it. Kellgren's skill is shown by the fact that he not only feels the smallest local change in temperature, fullness, muscular resistance, etc., even when these changes can neither be seen nor measured. This gift has been the primary cause that enabled him to achieve such brilliant results. It is certain that several of his pupils possess this power to a greater or lesser degree; but time alone can show whether any of them can equal or legitimately succeed Henrik Kellgren.

THE QUESTION OF "JUSTIFIABLE HOMICIDE."

BY CHARLES GREENE CUMSTON, M.D., BOSTON.

(Continued from No. 14, p. 467.)

THERE is one other cause which has been attributed to crimes from passion, whose importance I doubt very much. People have considered that one of the principal motives for these crimes is the taste for scandal and notoriety. They point out as a proof of their theory the dramatic attitude assumed by criminals from passion, either during the crime, or at the trial. It seems difficult to me to believe in the existence of such a motive. Criminals from passion occasionally do assume theatrical airs, but they merely borrow the external aspect of certain personages, while at the bottom of all their character remains unchanged. What ordinarily makes one suppose that these people are dramatic or theatrical in attitude is merely their own passion. No longer being retained by any consideration of conduct, they give vent to sentiments of abnormal violence and proclaim it widely. From this arises the analogy with the hero of the theater, who in reality is merely a criminal from passion copied from those of reality. Other than this we do not believe that the taste for dramatic notoriety has ever been the cause for the commission of a crime in a perfectly normal man, or at least we are unfamiliar with any such example.

Beside crimes from passion directly and immediately inspired by love or jealousy, one should also take into consideration crimes which have been committed merely to satisfy these passions. As an example, let us take a man who kills his mistress's husband during an attack of jealousy and afterwards commits suicide; this is a crime from passion. On the contrary he who kills his mistress's husband in order to marry her afterwards commits an ordinary murder. It is not suicide following the first crime which changes the nature of the crime, it merely proves the motive, namely, jealousy. It also indicates the character of the crime imposed by a passion, a crime from which the murderer can gain nothing and has no further interest for him. It is not the same in the second case to which we have alluded. There is no resemblance between a man who, during an attack of jealousy, kills his mistress, and of the one who in order to take a woman to himself becomes an assassin. One is a criminal belonging to a special class; he is certainly guilty and society should defend itself against him, but it should be done within a certain measure. The man that it must strike is normal; his sentiments are those of all decent people, only they have been possessed by a particular violence and were not moderated by a sufficiently strong will. The other type, on the contrary, is a criminal who has stolen or killed from love, but passion in this case is no longer an excuse, and at the utmost could only be used as an extenuating circumstance. Why is this? It is because the latter has abnormal sentiments; it is not merely the excessive development, I might say pathologic, of honorable and normal sentiments; it is the appearance of anti-social sentiments of the highest order, namely, the fact that the individual does not withdraw, in face of the crime, to satisfy his passion; he is subject to relapses and is a vulgar assassin.

These crimes may have numerous ends, and we will mention only a few examples. We have already spoken of crimes having for an end to procure money for a woman; urged on by her, or reduced to misery by her, a man will murder in order to procure money. In reality this is merely an instance in which the motive is one of personal gain, and the most that can be said is that a certain amount of leniency might be shown the criminal if passion deprived him of his ordinary will power when the act was committed. But these cases should not be classed among crimes from passion. Beside a murder perpetrated to procure money for the beloved one should be placed the murder which has for end the union of two lovers, and it is quite certain that this motive is the cause of many of these tragedies. Usually it is the woman who forces her lover to murder her husband so that they may be married afterwards. Her end is in the first place to be freer and also to legitimatize her love and proclaim it everywhere. It is also a crime which, in the idea of the perpetrators, should make them high in public consideration.

A woman has two means by which she can execute this project. She may either act herself, and then it is usually poison that she employs; or she may force her lover to kill her husband; and in order to attain this end she will employ all the means placed at her disposal, as has been recently illustrated by the female murderer Rogers, and her lover Perham. Then, again, she may excite her lover's jealousy, in which case the woman is simply a murderer in the ordinary sense of the term, while on the part of the man, the crime is one from passion. It may appear strange that the same crime may be one of passion as far as one of its perpetrators is concerned and not be as far as the other is concerned. It is, however, certain that it is not the crime, but the criminal, which is animated with passion, and one is consequently dealing with a subjective criterion, the motive which caused each of them to act at the time of the crime. It consequently results that, if this motive is not the same for each perpetrator of the same crime, the latter is not of the same nature as regards each one connected with it. The most extraordinary case is certainly a man killing his mistress's husband, when the latter is perfectly innocent and even is unaware of the tragedy; but, nevertheless, this happened in the Peltzer case which was tried at Brussels in 1882. Another peculiarity in this case was the fact that the assassin himself denounced his crime. Peltzer belonged to a good family, although personally he was deprived of any scruples. Being very intimate with a certain lawyer at Antwerp, he became amorous with the wife of the latter. The husband becoming aware of this asked him to break off all relations with him. Peltzer then started for America and appeared to renounce

his love. Sometime afterwards he came back and was so changed that no one recognized him, not even his former friend. He then brought the lawyer into an isolated house under the pretext of consulting him and then killed him. The house in which the crime was committed was too well chosen and too discreet, so the cadaver of the unfortunate lawyer was not found. From this fact his death could not be proven and his wife did not become the widow, but merely the wife of a husband who had disappeared and consequently she could not remarry.

What would have been a great success for another assassin, was a total failure for Peltzer. He was desirous of hastening things, and so wrote to the authorities at Brussels denouncing the crime and the place where the victim lay and so forth. The body of the unfortunate lawyer was found and the assassin very soon afterwards. The latter pretended that the murder took place during a moment of anger at the end of a discursion, but premeditation being absolutely established, the explanation was rejected. Peltzer had killed his victim with the hope of marrying his wife, who, for that matter, was in no manner an accomplice and did not even appear to love him.

We have thus passed in review all types of crimes from passion, but this does not imply that we have considered all crimes which are the consequences of love, jealousy, or hatred, because we have merely considered those which were directly inspired, and for this reason we have left aside abortion and infanticide, as well as duelling. It goes without saying that the criminals of this class are often of much interest, but unless one should greatly change the meaning of words, their crimes cannot be considered as crimes from passion.

Having now seen what we understand as a crime from passion, we will endeavor to distinguish it from those crimes with which it may be easily confounded and which I will term *crimes from pseudo-passion*. When they are carefully examined, their perpetrators will be found different from criminals from passion, and from the standpoint of criminality they may be placed in various categories. They are either irresponsible individuals or insane criminals; or, on the other hand, they may be ordinary murderers, fully responsible and guilty, which gives to a crime of cupidity or a rape the aspect of the crime from passion. We have endeavored to show that criminals from passion are far from being in a perfect condition of mental stability, and, in order to pass any kind of sentence upon them, it is necessary to prove that they had a notion of their acts.

The crime of an insane person may be confounded with a crime from passion in this way. Sometimes it is an ordinary insane person in whom ideas of persecution have taken on a peculiar form; he believes that his wife has deceived him, or he has been imposed upon by his mistress and he wishes to become avenged. Then, again, it may be jealousy which has altered the mind of an individual to such a point that it degenerates into a true case of insanity. Scientifically speaking, the subject is no longer merely a subject of jealousy, but is in reality a furious maniac. The question may be extremely difficult to decide, if a person afflicted by jealousy is in a condition of mind bordering on ideas of persecution. Among murderers there are many possessing weak minds; sometimes this weakness is made evident by an excessive susceptibility, and subjects afflicted with jealousy may even become provoked by a smile or derision. This insane fear of derision is one of the signs of a condition requiring an attentive examination in order to discover whether or not the accused is responsible.

Sometimes this mental weakness will become manifest by a particular facility to undergo suggestion, as may be seen by the following example: A workman, having laughingly said to a friend who was complaining of his wife: "When a man has a wife like that she should be thrown into the water"; the latter took the meaning seriously and threw his wife in. A crime may be so extraordinary, and at the same time so cruel, that magistrates are forced to extreme severity, but the crime is also so strange and so unexplainable that they hesitate to act for fear of wrongly sentencing an irresponsible person. Quite recently an abominable crime was committed in the little city of Fitthausen. A young and healthy husband, odiously mutilated his young wife, although no coquetry on her part could be a motive for the crime. When the criminal spoke of subjects foreign to his jealousy he reasoned correctly and quietly and nothing showed that he was insane, but when questioned as to the conduct of his wife his eyes became hyperemic; his countenance took on a hard and savage look and he accused the unfortunate victim of the lowest actions. His jealousy went as far as a paroxysm of insanity. Moreau of Tours has recorded a case of jealous insanity which took place in the small town of Balace. A landed proprieter by the name of Montée, blinded by an excessive jealousy, suspected that his wife was the mistress of a neighbor by the name of Baron. One day Montée hid himself behind a window in his house and fired a shot at his supposed rival, which instantly killed him. Immediately afterwards Montée took an axe and started towards the house of his victim. He went to the upper story where he found the victim's little girl about ten years old, seated in front of the fire. He broke her skull open with the axe. The assassin then started out to find his victim's wife, and going into a field, not being able to find her there, he slaughtered several sheep which were grazing. When leaving the field Montée went and hung himself on a neighboring tree.

In this case insanity is so evident that if the assassin had been arrested the question of responsibility would not even have been brought up and Montée would have been sent to the insane asylum, but it would appear to us that it was an instance of jealousy which was transformed into insanity.

Closely related to crimes from insanity there are

crimes from passion which in reality are merely crimes from alcohol. Intemperance goes arm in arm with *débauche*, and drunkenness only brings about wordy discussions. In December, 1902, the case of a certain Cormaire was tried in Paris. Cormaire was thirty-five years of age, whose father, an alcoholic, committed suicide during an attack of insanity. One evening he himself committed a crime during an attack of insanity which left no trace in his memory. Without any appreciable interest or provocation he pounced upon a *puella publica* and tried to cut her throat. Two days later, after a day of fever, he returned to the shop where he worked and read the account of the crime in a newspaper. Suddenly he was overcome by this detail, "the murderer had left his hat at the victim's house." The amnesia suddenly disappeared and he finally remembered the whole event. When arrested Cormaire was found absolutely irresponsible, but later on, during an attack of jealousy, he killed his mistress. Arrested again, he was submitted to another medical examination, and this time was considered responsible. It was, however, pointed out at the trial that Cormaire was not mentally well balanced, that he was the son of an alcoholic and an alcoholic himself, in other words a degenerate impregnated with alcohol. Insanity not being absolutely characteristic, at least for the last crime committed, caused the jury to render a verdict of guilty.

To sum up in cases of crimes committed by individuals who are recognized insane, the question of a sentence does not even come up, and criminal lunatics should be sent to asylums. For that matter there would be no legal interest to distinguish subjects of jealous insanity from those afflicted with ideas of persecution, like those of which we have spoken. If they have been made mention of here it is because occasionally they are acts strangely resembling crimes from passion, and a careful medical and psychologic examination can alone establish the fact whether or not the criminal is responsible.

Although it is frequently a delicate matter to characterize these crimes, which, from their nature, have the appearance of crimes from passion, how much more difficult it is for the Court and the jury to determine the nature of the crime when the accused affirms that he acted under the domain of passion, when in reality it was quite another motive which caused him to commit the crime. Innumerable are the crimes which take on the appearance of crimes from passion and which are in reality accomplished from cupidity, *débauche*, vanity, etc. The difficulty is to distinguish these crimes from true crimes from passion. When the accused appears upon the stand it is very frequently upon this point that the discussion turns between the government and the defence, namely, What is the motive which caused the murderer to perpetrate the crime?

Each will give his explanation. The defence pleading a blinding passion, while the government will uphold that the crime in question is not one of passion and has been committed by the accused for some interested motive.

Among the crimes having an appearance of passion and of interested motive we should first consider those of cupidity, such as the following example: Some twenty-five years ago a widow by the name of G. was a well-known character in the gallant world of Paris. She began to age and foresaw with terror the approach of the time when generous donators would no longer be in sufficient numbers to satisfy her needs. Her last lover was a very young and wealthy man, but without experience, and she resolved to attach him to herself for life. To accomplish this it was necessary to render marriage an impossibility for him, and, in order to attain this result, she resorted to a very simple means, namely, to disfigure the young man's face by vitriol so that he would be a subject of horror for all others. He then would be forever under her power. But with this plan she could not act herself and she consequently excited a certain X, a man of the people that she had taken for a lover. On a certain evening when the woman G. came home from the theatre with X, the young man already alluded to executed the crime which she had conceived, and inundated the young man with vitriol. She then took care of her victim with such a devotion that the Court had all the difficulty in the world to make her victim understand the guiltiness of his mistress.

Beside this crime, so extraordinary from its perversity and audaciousness, female vengeances are more frequently met with in which a disappointment in love is combined with the need of money. There are cases in which the pain is due to the departure of a lover, who certainly was inconstant, but who, more especially, forgot to give the indemnity hoped for by his mistress in case of rupture. The woman then threatens to make a scandal, and if this blackmailing scheme fails she sometimes carries her threats into execution. She finally poses as a victim of love. Such was the case of M. M., who, in 1880, avenged herself upon her lover who was on the point of getting married. She had hoped that for a long time to come, if not for always, he would attend to her needs, but when she heard of his marriage, she had vitriol thrown in his face by another woman over whom she had sufficient influence to make her execute the crime.

It is not always in illegitimate unions where cupidity takes the place of love, for beside *liaisons* of interest, there are also marriages for money, and here again we will meet with the so-called crimes from passion in which passion has never existed. A farmer, having sought the hand of a rich young woman in marriage, and after having hoped to obtain it, was so disappointed by the parents' refusal and so angered to see such an advantageous party escape him that he had the young girl meet him and, after having obliged her to accept him as a husband, plunged a knife into her abdomen.

Medical Progress.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY MYLES STANDISH, M.D., BOSTON,
AND
WM. DUDLEY HALL, M.D., BOSTON.

PROTOZOA.

DURING the last decade the protozoa, especially the pathogenic forms, have received considerable attention from investigators interested in the lower forms of animal life, and of these, the trypanosomes have probably been the favorite subject of study. Although the first of this group was described by Valentine more than sixty years ago, who found it in the blood of a salmon, and, although from time to time allied organisms have been identified, sustained work in this direction was not begun until some years later. When Evans in 1880 demonstrated that a disease of camels and horses, known as surra, was dependent upon the presence in the blood of the animal, of a protozoal organism, there was quickly instituted a series of experiments which had, as a result, an appreciation of the proper relation which should exist between plant and animal life as an exciter of infectious diseases. This organism, the trypanosome, may be briefly considered as a fusiform, more or less elongated body, about the length of the diameter of a blood corpuscle, possessed of a fin-like membrane, longitudinally, and a terminal flagellum. It was soon found that other diseases of animals as, nagana, mal de caderas, dourine, etc., might be ascribed to other members of this group. These discoveries attracted but little notice in the medical world until Dutton identified a trypanosome in the blood of a European, who had resided in the Gambia region, and Castellani showed the significance of its presence in the cephalo-rachidian fluid of negroes who were suffering from the disease known as "sleeping sickness." Thus far the conditions set up by the parasite have been met with, for the most part, in Africa, Asia, and South America; but Morax, in a recent paper,[1] has published the results of his work in the experimental pathology of the disease, paying especial regard to the ocular manifestations. He was struck by resemblances between certain corneal appearances in dourine and the well known lesions of interstitial keratitis observed in syphilis.

Nagana, the tsetse-fly disease, affects all domestic animals and many that are wild, and is invariably fatal to the horse and dog, although a certain percentage of cattle recover. The duration may be several weeks or several months, and in case of recovery a certain immunity seems to be established in the animal in question for this particular form, but not for others of the group, thereby suggesting a certain specific character. Man is naturally immune, probably through some peculiar property of his blood plasma. Symptomatically there is noticed fever, lymph infiltration of subcutaneous tissues of neck, abdomen and extremities, destruction of red blood corpuscles, extreme emaciation, blindness and the constant presence in the blood of a parasite which was identified by Bruce in 1894 and which bears his name. There seems to be but little doubt as to the rôle of the tsetse fly in the transmission of the disease, as infected and non-infected animals may run together with impunity in the absence of this particular fly. The process among the smaller mammals is quite acute and ocular complications are rare. The contrary obtains among the larger animals, the process being subacute and eye lesions more frequent. Here will be noticed a turbid, aqueous, fibrinous deposit in the anterior chamber and upon the iris, corneal opacities and a mucopurulent conjunctivitis. The parasite has been found in the conjunctival secretion and in the anterior chamber. Edema of the lids and face has occasionally been mentioned as occurring. In the case of the horse and ass the cornea has become quite opaque, even taking on the tint of porcelain, yet, notwithstanding the apparent severity of the corneal condition the opacities may disappear in the course of a few weeks.

Surra, the term implying a rotten or diseased condition, is a malady of horses and camels in India, although not peculiar to that particular country. Clinically it somewhat resembles nagana, as there exists a sort of pernicious anemia, fever, intermittent or remittent in type, emaciation, edema and lesions of eyes and lids. Evans, in 1880, found in the blood of infected animals, a trypanosome which now bears his name, and by the inoculation of which he has been able to reproduce a similar condition in the dog and horse. This organism so closely resembles that of Bruce, morphologically, that for differentiation it is necessary to study its cultural developmental characteristics upon some proper medium. Some other genera of biting fly than the tsetse must be responsible for its transmission, as infection may occur in regions where the tsetse is unknown. During a buffalo epidemic in Java a mucopurulent conjunctivitis and keratitis was frequently noticed. Five dogs became "blind," as the result of a hyena hunt. Among the cattle ocular complications take the form of a blepharo-conjunctivitis and keratitis, although blindness is rare. The disease is apt to pursue a rapid course, eventually terminating in blindness and death. In the case of laboratory animals, eye lesions are usually external and the organism will be found in the secretion.

Souma, a disease of cattle and horses in the Soudan, has been found to be due to a special parasite, the trypanosome Cazalboui, which, however, does not affect rodents or dogs. Corneal disturbances were noticed in an ass that had been inoculated with infected blood from an animal of like species. The upper half of each cornea became cloudy, and later a condition, somewhat resembling an ulcerative pannus, appeared, but absorbed before the death of the animal. There were no parasites found in the exudate.

Mal de caderas is the only trypanosomatic disease thus far recognized upon the American continent, is prevalent among horses in South Amer-

[1] Ann. d'Oculist., Dec., 1906.

ica and receives its name from eventual paralysis of the hind quarters before the death of the animal. Although edemas are usually absent, clinically, it resembles surra and nagana. The ass and mule resist, but dogs are susceptible, as well as rats, mice and other small rodents. It is apt to take on a mild type in the case of the larger animals. The parasite was first recognized by Elmassian in 1901 and received the name, trypanosoma equinum. As regards the ocular disturbances, it will be noted that the lids are swollen, there is chemosis and a foul mucopurulent discharge. Upon the cornea will be seen milky white spots, irregularly distributed and poorly outlined, resulting from a diffuse superficial interstitial keratitis, which, however, frequently absorbs, as does the hypopion, if present. Similar conditions obtain in dogs and rabbits, if inoculated.

Dourine is a disease of horses, not limited to the tropics, as it has been met with in many parts of Europe. Although due to a trypanosome in the blood, the equiperdum, transmission is believed to be due to sexual contact. Clinically it resembles the other diseases of the group, and paralysis usually precedes death. Conjunctivitis, keratitis, hypopium and lenticular opacities sometimes occur and the presence of the organism may be demonstrated in the conjunctival secretion of an inoculated rabbit. One or two months after intraperitoneal inoculation of several dogs and an ass interstitial keratitis with corneal opacities developed resulting in complete blindness. When the iris was visible it was seen to be inflamed and covered with a purulent or fibrinous exudate. The ciliary body was found to be involved. Anatomically the corneal opacities are found to be due to the presence of mononuclear leucocytes and trypanosomes in the interlamellar spaces and in the anterior chamber. The posterior segment of the globe was less affected. The dogs all died before showing any amelioration of the ocular symptoms. In the case of donkeys, opacities that may have developed may rapidly disappear, although if there is a tendency to ulcer formation, the inflammatory process may go on to panophthalmitis.

Human trypanosomiasis. — For a long time it was supposed that man was immune to this form of infection, and this is true in some instances, as, for example, surra, nagana, etc. Dutton, however, in 1901, recognized as a trypanosome, an organism which he detected in the human blood and which he named Tr. gambiensis. It has likewise been found in the cephalo-rachidian fluid. Following the invasion there appears intermittent fever with anemia, malaise, erythematous lesions and cutaneous edema. Somnolence and paralyses appear later. The ocular symptoms are few and unimportant. There may be a feeling of fatigue and unsteadiness of the type when reading, which will pass away after rest, providing it does not depend upon an error of refraction. The veins at the fundus may be somewhat enlarged. The conjunctival reflex is one of the last to disappear, and when this happens the prognosis is bad. Collins, who examined one of Manson's cases, stated that the fields were normal, pupils reacted and the media were clear. At each macula there was a superficial area of atrophic choroiditis, with pigment modification. In the right retina were some whitish, circular spots at a deeper plane than the vessels, and at each periphery were numerous spots, suggesting choroidal atrophy, some being more or less pigmented. Papilla normal. No hemorrhages. With such appearances, the possibility of a pre-existing specific chorio-retinitis should be considered.

Spirocheta pallida. — At the meeting of the German Ophthalmological Society, in 1905, Axenfeld, during the discussion of a paper on parenchymatous keratitis, and having in mind certain conditions which obtain in leprosy, stated that as we did not know the pathogenic factor causing syphilis, we should not exclude it from a clinically healthy-appearing cornea. Since that time, however, Dr. Greeff and others have been able to verify this statement, and as the result of work carried on with Hoffman, and also independently with Clausen, he was able to announce at a similar meeting in 1906 that he had been able to successfully inoculate the eyes of apes and rabbits, so that a few weeks later a tongue-shaped opacity appeared, which might seem to extend from the limbus centralwards. In the clear corneal area, in advance of the opacity, the spirocheta pallida could be detected without difficulty, in fresh cases, where they seemed to easily penetrate and multiply, whereas the opaque area had evidently been a battleground, where had taken place the death struggle between the previously existing spirochetæ and the thronging leucocytes. In this contest the odds seemed to be rather with the leucocytes, in the case of rabbits, as the manifestation seemed to be rather local in character; on the other hand, however, the greater diffusion of the disease and its closer resemblance to the analogous condition in man, in the case of the apes, rather suggested a supremacy in the pathogenic organism. As long ago as 1879 Klebs claimed that syphilis could be produced in apes, but this statement attracted very little attention at the time, and it was not until several years later that interest was sufficiently aroused by experimentation, undertaken by Metchnikoff, Roux, Neisser and Finger. Although anthropoid apes were at first supposed to be necessary, it was found that other species, which bore a still more remote relationship to man, were likewise susceptible to a somewhat atypical form of the disease. In 1881, Hansell, by the inoculation of rabbits with human syphilitic material, obtained appearances in the cornea and iris, closely resembling those observed in man. Schucht, quite recently, by using an emulsion of syphilitic inguinal gland, which he introduced into the eyeball, has obtained a parenchymatous keratitis and condylomatous iritis. Many spirochetæ were detected in horizontal corneal sections, but none in cross sections. He also succeeded in carrying the disease from apes to rabbits. Several contributions to the study of hereditary syphilis and the relation of the spir-

ochetæ thereto have appeared quite recently. Gouven has found the pallida in an apparently healthy cornea while examinating a syphilitic fetus. Schlimpert, from the examination of a macerated fetus and a prematurely delivered child, believes the organism to be less frequently found in the eye, as compared with other organs. They were, however, more numerous about the choroidal vessels than in the sclera or retina. They were also frequent in the deeper layers of the cornea, in the retrobulbar portion of the optic nerve and in the trunks of muscles. The lens and vitreous were found to be free. The contention between different zoölogists, as to whether the spirocheta pallida, or triponema pallidum, as suggested by Schaudinn, is to be considered as of the protozoa or not, is quite as interesting as is its etiological relation to syphilis. According to Schultz, it may be stated that this much of our knowledge regarding it is beyond dispute. It is a spiral organism, from four to twenty microns long and four tenths broad, with pointed ends, each of which possesses a single flagellum. The spirals are quite close and regular, averaging one micron in length, and liable to disappear when quiescent. There is neither an undulating membrane nor nuclear differentiation. The single polar flagellum, the large number of flexible spirals and the probability of longitudinal division rather favor its protozoan nature.

The following articles have been utilized in the preparation of this report: Morax: "Les affections oculaires dans les trypanosomiases," *Ann. d'Oculist.*, December, 1906. Scherber: "Ueber Spirochaetenerkrankungen," *Zeitschrift für Augenheilkunde*, February, 1907, as both contain excellent bibliographic references. The attention of the reader is also directed to a paper on "Trypanosomes," by Novy, which may be found in the first two numbers of the *Journal of the American Medical Association* of the current year, and also to one on the same subject by Greeff, contained in the *Reports of the German Ophthalmological Society* for 1906.

Book Reviews.

Essentials of Chemical Physiology. By W. D. HALLIBURTON, M.D., LL.D., F.R.S. Sixth edition, 258 pages. London and New York: Longmans, Green & Co. 1907.

In this sixth edition of his "Essentials of Chemical Physiology," Professor Halliburton has thoroughly revised this well-known book. Many of the parts, especially those concerned with the proteins, have been rewritten, and those concerned with coagulation of the blood and with respiration have been amplified to include the new knowledge in these subjects. The general character of the book remains unchanged and is too favorably known to need comment.

Essentials of Human Physiology. By D. NOEL PATON, M.D., B.Sc., F.R.C.P. Second edition, 425 pages. Chicago: W. T. Keener & Co: Edinburgh and London: William Green & Sons. 1905.

As the title of this book indicates, it is a statement of what Professor Paton regards as the essentials of the physiology of man. The book is characterized not only by an emphasis on the main facts of the science, but by simplicity and clearness of statement and by many illustrations. The ingenious diagrams illustrating physiological processes may be regarded as a unique feature. The book is intended, according to the author, to supplement the practical work and demonstrations from which alone a real knowledge of the subject can be gained.

Physiology of the Nervous System. By J. P. MORAT. English translation by H. W. SYERS. 680 pages, 263 illustrations. Chicago: W. T. Keener & Co. 1906.

This translation of the portion on the nervous system in Morat and Doyon's great "Treatise on Physiology" places before English readers an important comprehensive study of the nervous system. It summarizes in an encyclopedic manner the knowledge both of the structure and the function of the nervous system. The most elementary structure, the neuron, is first considered: its various forms, its conditions of irritability and the nature of nervous conduction. There is in this connection a discussion of the methods of stimulating nerves and the energies which can be evoked by stimulation.

Following the discussion of the nervous element, there is a section on the simpler relations of the elements, in reflexes and in segmental arrangements of reflex functions. The functional determinations of the cranial nerves are treated with special thoroughness.

The relations of impulses in reflexes, *i. e.*, inhibitions and augmentations, and the classification of general nervous functions, such as thermic and trophic effects, are next considered.

The transmission of impulse in the fiber tracts of the spinal cord, the functions of the sympathetic system (very clearly and fully expounded) and the important activities of the medulla are presented, along with an interesting discussion of consciousness and unconsciousness and the degrees of consciousness which may be recognized. Following this is the physiology of the cerebellum, the optic thalamus, corpora striata and the hemispheres, with a complete consideration of cerebral localization.

The volume will be of especial value to physiologists, neurologists and medical students especially interested in the nervous system and its functions. The final chapters in the innervations of the various sense organs, combined with its other features, make the book an important one also for the psychologist.

American Practice of Surgery, a Complete System of the Science and Art of Surgery. By representative surgeons of the United States and Canada. Editors, Joseph D. Bryant, M.D., LL.D.; Albert H. Buck, M.D., of New York City. Complete in 8 volumes. Volume III. Profusely illustrated. New York: William Wood & Co. 1907.

This work improves as successive volumes come from the press, and the list of contributors to Volume III speaks for sound writing, for we read the following well-known names: Eve of Nashville; Horsley of Richmond; Mason of the Army; Oliver of Cincinnati; Painter and Simmons of Boston; Park of Buffalo; Peters and Primrose of Toronto; Rambaud of New York, and Thomas of Philadelphia.

Volume III includes parts 11, 12, 13. Part 11 deals with poisoned wounds by Mason, including the bites and stings of animals and insects. This is an original and striking contribution, and the pages are well illustrated. Then there follows a chapter on Rabies, — a brief, satisfactory essay by Rambaud.

The bulk of the book — parts 12 and 13, 697 of the 760 pages — is taken up with the chapters on injuries and surgical diseases of bones and joints. Eve writes well on fractures; Thomas on pseudarthrosis; Peters on inflammation of bone; Park on noninflammatory affections of bones; Horsley on syphilis of bones; Simmons on bone tumors; Painter on nontuberculous and nontraumatic chronic inflammations of joints; Primrose on bone and joint tuberculosis, and Oliver on wounds of the joints.

How shall the unfortunate reviewer briefly sum up this immense mass of admirable writing? Suffice it to say that the writing is admirable; that the views expressed describe the best and most recent convictions on the pathology and treatment of these difficult subjects, and that this handsome volume certainly finds its place as one of the most important contributions to recent surgical literature.

Treatment of Caries of the Spine. Treatment of Congenital Dislocation of the Hip. By Dr. F. Calot. Translated by Dr. P. Ewald, with an introduction by Prof. D. Oscar Vulpius. Stuttgart: Published by Ferdinand Enke. 1906.

It is unusual to receive the writings of a French medical author through the medium of a German translation and endorsed by a German professor. This speaks both for the excellence of the original as well as for the energy of the German publishers.

Dr. Calot some years ago called attention to the rectification of the deformity of Pott's Disease by forcible correction. In the present monograph the means of the application of plaster bandages to be used in the treatment of tuberculous vertebral diseases are well described. The writer advocates the repeated injection of the developed abscesses with small doses of creosote without incision.

The statistics of Calot in the reduction of congenitally dislocated hips are usually good. The method of reduction may be briefly described as a development of the well known Paci-Lorenz method with a different position of the limb in after-treatment, this position being similar to that recommended by Dr. Mueller, of Chicago. In a few obstinate cases Calot has employed (instead of incision) a dilator for the constricted capsular ring, similar to a curved sinus dilator, introduced into the sac through a small skin incision.

Technique Orthopédique. By P. Redard. Paris: Published by F. R. de Rudeval. 1907.

A number of excellent books on orthopedic surgery are to be found in English, French and German. Articles, monographs, special journals in these languages and in Italian increase the literature of the specialty to such an extent that a writer on the subject requires much diligence and mental activity if he desires to keep abreast of the progress in his branch. It is therefore singular that in a specialty which demands particular acquaintance with the devising and use of apparatus there should be no book especially devoted to this especial part of orthopedic work. It is fitting that at last such a publication should appear and should come from France, the starting place of orthopedic surgery.

The book is useful in giving to the reader detailed descriptions of the apparatus and mechanism in use in the practice of orthopedic surgery, including plaster bandages.

Lateral Curvature of the Spine and Round Shoulders. By Robert W. Lovett. Philadelphia: P. Blakiston's Son & Co. 1907.

To the readers of the Journal the admirable work of Dr. Lovett is familiar as many of his articles embracing his investigations on the subject of scoliosis were published originally in the columns of the Boston Medical and Surgical Journal. These writings have been amplified and are published in an excellent monograph which can be cordially recommended to all specialists and to those interesting themselves in the study and treatment of curvature of the spine.

Besides a statement of his original investigations as to the normal movements of the spinal column the book contains excellent descriptions, amply illustrated, of the gymnastic exercises employed in correcting cases and in measures for correcting by means of plaster jackets.

A Manual of Surgery for Students and Physicians. By Francis T. Stewart, M.D., Professor of Surgery, Philadelphia Policlinic; Associate in Surgery, Jefferson Medical College; Out-Patient Surgeon to the Pennsylvania Hospital, etc. With 504 illustrations. Philadelphia: P. Blakiston's Son & Co. 1907.

This convenient volume of 778 small, closely printed pages is a compendium of well recognized views on surgery, and will doubtless be useful to students.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, OCTOBER 10, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

POPULAR LECTURES ON INSANITY.

IN this issue of the JOURNAL we publish papers by Dr. P. C. Knapp, on Heredity, and Dr. H. R. Stedman, on Popular Lectures on Insanity. Both are subjects little understood and, therefore, regarding which most erroneous ideas prevail in the public mind. It will be remembered that last year lectures on the general subject of insanity were given in New York under the auspices of the New York Psychiatrical Society which were semi-popular in character. They were given in the Academy of Medicine, and were intended for physicians and such others as might care to learn of recent opinions regarding the always important subject of mental alienation. These lectures were a success, although possibly they did not reach the rank and file of the people. During last winter at the Harvard Medical School a series of popular lectures was given on a wide range of subjects in medicine, and the appeal made, particularly to the laity, to attend. Although the attendance varied somewhat, as might have been expected, from the differing popular interest of the various subjects presented, nevertheless, it was altogether gratifying and encouraging to those having the matter in charge, and demonstrated the desirability of continuing a similar course of lectures another winter. Through an oversight, rather than through intention, no lectures on the general subject of insanity were included in this course. This omission it is proposed to supply this winter.

In the paper by Dr. Stedman, read before the American Medico-Psychological Society in Washington, it is clear that both the importance and the difficulties of offering such a course of lectures to the laity are fully appreciated. The time, we believe, has come to make a more vigorous attempt than has heretofore been done to remove the curious misconceptions and morbid ideas regarding mental disturbance which have so long filled the popular mind. The subject is a difficult one to present; our knowledge is still vague; classifications are chaotic, and the popular impressions of the insane person are so deep seated that it is not to be supposed they will easily be removed, as, for example, has the fear of tuberculosis. What such a course of lectures as Dr. Stedman proposes should accomplish is to bring before the public certain ascertained facts, and particularly to take every reasonable means of allaying popular fear. The dread of commitment to a hospital for the insane is also still widespread, and the conception of treatment in such institutions wide of the facts. The public should be educated in these matters and at the earliest possible moment. There is, perhaps, no better means of accomplishing this result than by the means which Dr. Stedman suggests.

We are glad also to call attention to Dr. Knapp's conservative interpretation of statistics regarding heredity. There are few subjects about which the public at large, and even the profession, have vaguer notions than this of the significance of the hereditary transmission of disease, and many sins have certainly been committed in its name. This subject should also be considered in popular lectures, but only at the hands of a person who combines much knowledge and experience with the saving grace of tact and good judgment.

In general, we are altogether in favor of the plan outlined by Dr. Stedman, and are confident that good will ultimately come from the judicious dissemination of knowledge regarding the causes, course and treatment, both in institutions and at home, of the various forms of insanity.

CLOSING OF CAMBRIDGE SCHOOL OF NURSING.

IN our issue of May 25, 1905, we commented editorially on a school of nursing, which was at that time being established in Cambridge, Mass. We said, in part, " We have on various occasions commented on this tendency (namely, the tendency to exalt the work of nursing to the rank of a so-called liberal profession) and expressed a degree of skepticism regarding this expansion of the work of nursing. . . . In the minds of those

promoting the further education of nurses, it is clear that greater efficiency is to be attained by the new method than by the old. We have no desire to express an opinion on this point, but we are convinced that the success of the new movement cannot be assured until many years of experience have passed."

It has been announced within a few days that this school, auspiciously begun two years ago, has been closed for lack of students and proper support. When the establishment of this school for the training of nurses was agitated, it was designed to lay special stress upon the educational side of nursing, and the school was in some respects modeled after that at the Waltham, Mass., Hospital, which has been conducted for many years with great success, by Dr. Alfred Worcester and his colleagues. This was also the time when the question was agitated as to the desirability of nurses paying for their education, rather than being paid for their services. In pursuance of the general plan that nursing should be regarded in the light of a liberal education, a suitable house was secured in Cambridge, and the school was opened in October, 1905, with eight students. A charge for tuition of $150 was made for the first year, and $75 for each of the succeeding years of the four years' course. A year later but six pupils applied for instruction, and this year there have been seven applicants, too few to make possible a further continuance of the work in the estimation of the executive committee. Of the twenty-one students enrolled since the opening of the school, nearly one half were unable to pay the fees at required intervals and concessions were necessarily made. The course was then reduced to three years and six months, and the price of tuition also reduced, but this also failed to bring up the numbers. It is reported that there has been some difficulty of late in filling the Waltham Hospital School for Nurses, and, in general, the plan of charging nurses for their tuition has given place to the method formerly in vogue.

We bring this matter up again at this time, in the first place, to express our regret that this commendable, if somewhat chimerical, movement for the higher education of nurses has failed. More important than this, however, is the indication it gives regarding the general status of nursing in this and, no doubt, in other communities. As we have frequently had occasion to say, we have long felt that the exaltation of nursing to the status of a liberal profession, as some of its advocates seem to desire, is a mistake. There is as yet no evidence that young women in appreciable numbers will be willing to devote four years to training as nurses, in the meantime paying for their tuition; this experiment, undertaken at Cambridge, certainly does its part in bearing out this statement. There is small doubt in our mind that the limit of the training of nurses has been reached, and that the wave of enthusiasm for more elaborate teaching has begun to recede. The Cambridge School of Nursing, which has just closed its doors, was a product of this over-enthusiasm. There was every reason to think at that time, and we have no doubt that the executive committee were imbued with the opinion, that there was need of just such a training school and that applicants would be forthcoming to render it an unquestioned success. Predictions as to its outcome would have been fruitless, and we mention the failure of the movement merely as indicative of the somewhat abnormal condition of the popular attitude toward the training of nurses. We shall, no doubt, continue to have trained nurses who have long since proved themselves indispensable to medical practice, but both for their sakes and for that of the medical profession, it is very desirable that the limitations of their training should be defined as sharply as possible.

MEDICAL NOTES.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Oct. 9, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 29, scarlatina 37, typhoid fever 20, measles 8, tuberculosis 31, smallpox 0.

The death-rate of the reported deaths for the week ending Oct. 9, 1907, was 18.48.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Oct. 5, 1907, was 207, against 227 the corresponding week of last year, showing a decrease of 20 deaths and making the death-rate for the week 17.71. Of this number 107 were males and 100 were females; 203 were white and 4 colored; 149 were born in the United States, 56 in foreign countries and 2 unknown; 45 were of American parentage, 136 of foreign parentage and 26 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 30 cases and 1 death; scarlatina, 32 cases and 1 death; typhoid fever, 20 cases and 0 deaths;

measles, 10 cases and 0 deaths; tuberculosis, 50 cases and 20 deaths; smallpox, 0 case and 0 deaths. The deaths from pneumonia were 21, whooping cough 0, heart disease 16, bronchitis 3 and marasmus 11. There were 6 deaths from violent causes. The number of children who died under one year was 66; the number under five years, 85. The number of persons who died over sixty years of age was 45. The deaths in public institutions were 61.

There were 3 cases and 3 deaths reported from cerebrospinal meningitis during the week.

ANNUAL MEETING OF NEW HAMPSHIRE SURGICAL CLUB. — The twelfth annual meeting of the New Hampshire Surgical Club was held at the Pemigewasset, Plymouth, N. H., Sept. 18, with a good attendance of members and their ladies. Dr. Joel F. Goldthwait, of Boston, read an interesting paper on "Non-Tuberculous Diseases of the Joints." This paper was discussed by Dr. Gile, of Hanover, Dr. Smith, of Hanover, and Dr. Prouty, of Keene. Dr. E. L. Bell presented a paper of much importance, "A Medico-Legal Case." The President, Dr. Frank Blaisdell, of Goffstown, gave the annual address on "The New Hampshire Surgeons from 1800 to 1900." The annual banquet was held at eight o'clock in the evening, and was followed by toasts: "The New Hampshire Surgical Club," Dr. Frank Blaisdell, "Our State Society," Dr. John M. Gile, "The General Practitioner and the Specialist," Dr. Goldthwait, "The Clergyman and the Doctor," Rev. Doran, "The Auto and the Doctor," Dr. James Greely, "The Surgeon in the Lumber Camp," Dr. E. L. Bell, "The Doctor's Vacation," Dr. Kingsford. The following officers were elected for the ensuing year: Dr. N. W. McMurphy, of Gilmanton, president. Dr. A. W. Shea, of Nashua, vice-president. Dr. J. M. Town, of Manchester, secretary and treasurer.

NEW YORK.

ROOF GARDEN FOR ST. LUKE'S HOSPITAL. — Plans have been filed with the Building Department for an addition to St. Luke's Hospital, in the shape of an elaborate roof garden on the Muhlenberg pavilion of the central administration building, which is to cost $20,000.

LAWS REGARDING SALE OF COCAINE AND ALLIED DRUGS. — In the new law which recently went into effect in the State of New York which makes it a penal offense to sell at retail cocaine or any preparation containing it except upon the written prescription of a duly registered physician, the same restrictions are enforced regarding alpha and beta eucaine. Proper safeguards are also prescribed for the wholesale disposal of these drugs.

BATHS FOR WORKING PEOPLE. — In the section on "Professional Hygiene and Care of the Working Classes" of the International Congress of Hygiene and Demography at Berlin, Dr. Simon Baruch, professor of hydrotherapy in the medical department of Columbia University, read a paper on Sept. 25 on "Baths for Working People," in which he made a strong plea for free cleansing baths. In the course of it he said that the river baths supplied by municipalities, while refreshing and pleasant, were not sanitary in the true sense of the word, and were to be regarded rather as a luxury than a necessity. The fact that propriety demands that women be entirely clothed, and men partially covered, militates against their capacity for cleansing. The application of soap is impossible, and without soap there can be no removal of impurities.

FEES OF EXPERTS IN THAW TRIAL. — The following amounts, for the services of alienists and experts in connection with the Thaw case, have been sanctioned by the controller: Dr. Carlos F. MacDonald, $6,300; Dr. Austin Flint, $5,315; Dr. William Maybon, $3,987; Dr. Robert C. Kemp, $3,102; Dr. A. R. Diefendorf, $990; Dr. William B. Pritchard, $420; Dr. Albert W. Ferris, $380; Dr. William Hirsch, $420; Dr. R. A. Witthaus, $142; Dr. August Hoch, $90.

BEQUESTS. — By the will of the late D. Willis James, of New York, $1,000,000, in sums of $100,000 to each, is bequeathed to ten universities, benevolent societies and institutions, among which is St. Luke's Hospital.

BEQUESTS TO CHARITIES. — By the will of the late Gen. Charles E. Furlong, of New York, more than $150,000 is left to charities. Among the institutions receiving $5,000 each are the following: Nursery and Child's Hospital, New York Infirmary for Women and Children, New York Foundling Asylum, and the New York Infant Asylum.

A LECTURE ON TYPHOID FEVER. — A lecture was given Oct. 5 at the Library Building of the Medical Society of Kings County, in Brooklyn, by Dr. Darlington, President of the Health Department, under the joint auspices of the Kings County Medical Society and the Brooklyn Institute. The attendance was so gratifying that Dr. Glentworth R. Butler, the president of the Medical Society, said, in introducing Dr. Darling-

ton, that ample encouragement was afforded for the repetition of similar lectures on topics pertaining to the public health in the future. The subject of the evening was "Typhoid Fever and Other Infectious Diseases; How They are Spread," and the keynote of the lecture was given in the opening sentence: "In speaking on the subject of contagious diseases one should have the fact firmly fixed in his mind that the statement that a disease is of an infectious character carries with it the thought that it is also absolutely preventable." In the Borough of Brooklyn, Dr. Darlington said, there had of late been a steady decrease in the number of cases of typhoid reported. In 1905 there were, in 1906, 1,200, and this year, so far, 600. In a city like New York, while contagion might be held in check, it could never be wholly eliminated. Many cases of infectious disease went untreated and so escaped detection, and one of the worst phases of the situation was the neglect of some physicians to report their cases. Co-operation of each individual and physician in the community was necessary to assure any efforts towards ideal attainments, and co-operation could only be reached by educating the public as to its vital importance. Public lectures, the public press, co-operation with philanthropic societies, printed instructions and personal efforts were all valuable aids. In the course of his remarks, the lecturer made a strong plea for a filtration plant to meet the requirements of the city, and deplored the fact that all improvements looking to its welfare moved so slowly and met with so many obstacles. In conclusion, he announced that the corner-stone of the new Board of Health Building, which is to be erected in Brooklyn, and which he stated would be the finest building of its kind in the world, would probably be laid in December.

Obituaries.

HENRY WATSON DUDLEY, M.D.

In Memoriam.

From time immemorial it has been the custom to mingle with laments for the dead eulogies of their well spent lives. We regret that the time has come when it becomes our sad duty to record the death of Dr. Dudley.

We realize that we have not the gift of language or power of speech to correctly portray his strength of mind, the nobility of his character and those qualities he possessed, which are not easily expressed in words, that endeared him to so many of us.

There are three elements which unite to produce a career like Dr. Dudley's. That which his ancestry gives; that which opportunity gives and that which he himself develops.

Among his distinguished ancestors were Thomas Dudley, the Colonial Governor, Rev. Samuel Dudley, who settled in Exeter, N. H., in 1650, and married the daughter of Governor Winthrop; Stephen Dudley, who was born in Exeter and married the daughter of Hon. John Gilman; Deacon Stephen Dudley, who settled in Gilmanton in 1774 and was one of the petitioners for the first town meeting in 1776, and was also one of the original members of the church formed in 1774; Dr. William Smith, the pioneer doctor of Gilmanton, and for some time the only doctor nearer than Concord, whose practice extended out thirty miles, when the only guides to conduct him through the wilderness were spotted trees. He was Dr. Dudley's great-grandfather.

Dr. Dudley was educated in the public schools of his native town, fitting for college at Gilmanton Academy, entering that institution when seventeen years of age and graduating in the Class of '51. He taught in the high school a few years and served as member of the School Commission of Belknap County, N. H., and also as member of the State Board of Education of New Hampshire, in 1861, 1862 and 1863. He taught in Culpepper, Va., at the time of the famous John Brown raid in 1859.

He took his first course of lectures at Dartmouth Medical School, and completed his course in medicine at Harvard Medical School, graduating in March, 1864. He was a member of the Hatherly Medical Club and was identified with the Massachusetts Medical Society since 1866, and among the most prominent in the District Society, having served as its president and held other important offices, being a Counsellor from 1883 up to the time of his death.

He was affiliated with the Masonic fraternity, being a Knight Templar. He did not seek public office, but served on the School Board of Abington during the past ten years of his life, rendering valuable service to the educational interests of the town.

He was Medical Examiner for the second Plymouth District, having held that office since 1890, succeeding Dr. J. C. Gleason. He was a member of the Massachusetts Medico-Legal Society since Feb. 4, 1891. He was Professor of Pathology at Tufts College Medical School, from 1893 to 1900, and lecturer on Legal Medicine from 1901 to 1906. Noteworthy among his characteristics were the interest he took in medical meetings, his ethics and his supreme contempt for the unethical, his devotion to scientific knowledge and his aversion to hypocrisy and fraud.

He was liberally endowed with the most attractive qualities. Strong and active in mind and body, he could assert and express himself with power and force when the occasion required. The duration of his life, the usefulness of his labors, the elevation of his sentiments, and the nobility of his character united to form an attractive personality and a highly instructive and admirable career.

Resolved, That while we are ever mindful of the

uncertainty of human existence and the changes that are constantly going on in our midst, we desire to express to the family of the deceased our appreciation of his superior talents and his noble character.

Resolved, That we extend our heart-felt sympathy to the family of the deceased.

GILMAN OSGOOD, M.D.,
FRED J. RIPLEY, M.D.,
A. ELLIOT PAINE, M.D.,
Committee on Resolutions.

At a meeting of the Massachusetts Medico-Legal Society, held in Boston, Oct. 2, 1907, it was voted that the above resolutions be adopted and a copy furnished the BOSTON MEDICAL AND SURGICAL JOURNAL for publication.

OLIVER H. HOWE, M.D.,
Recording Secretary.

ALFRED H. GOULD, M.D.

DR. ALFRED H. GOULD died Oct. 2, after an illness of about one week, of an acute infection. Dr. Gould was born in Medford, Mass., and was thirty-four years old at the time of his death. He graduated from Harvard College in 1896 and from the Harvard Medical School in 1900. He thereafter served as a surgical house officer at the Massachusetts General Hospital, and after leaving that institution devoted much time to work in the laboratory and to experimental research on surgical subjects. The main result of this industry was a volume entitled "The Technic of Operations upon the Intestines and Stomach," published by the W. B. Saunders Company in 1906. Dr. Gould had recently been appointed an assistant in surgery in the Harvard Medical School and gave high promise of a successful surgical career. Through the book which we have mentioned he was coming to be widely known, and his course given at the Medical School on operative technique was sought by many practitioners, particularly those connected with the United States Navy. In his death the profession loses an industrious student, a teacher of promise, and a man from whom much might have been expected in the future.

2. Einhorn says that flatulence may be associated with the stomach alone, or with the intestine. When primary it is not caused by fermentation, but by swallowing of air. The sphincter muscles of the digestive canal are principally affected. It may exist for a long time without serious consequences. In acute and chronic gastric catarrh there is a real increase in the amount of gas in the stomach and a lessened absorption of it. Flatulence can be lessened by distracting the attention of the patient from his own sensations. When it is secondary it results from cardiac, circulatory, or respiratory diseases, and the relief by belching is rather imaginary than real. In primary flatulence treatment consists in the effort not to belch, with a simple diet and avoidance of beverages and foods that produce gas.

8. Rogers and Torrey have prepared a specific antiserum by inoculating animals with increasing doses of gonococci, at first devitalized, but finally using living organisms, grown on ascitic agar. The serum of these animals will agglutinate gonococci in high dilutions. They prefer a polyvalent serum, made from several strains of gonococci. This serum has been used in a series of 98 cases of gonococcal arthritis. They found the serum efficacious in 80% of the cases in a fairly acute stage. In chronic cases the results are not so encouraging, but as a rule there are here actual structural changes in the joint. They found the serum useless in acute and chronic urethritis and in gonococcal conjunctivitis. In epididymitis, salpingitis and iritis they think the outlook is promising.

12. Fleischman and Butler employed the method of Wasserman for demonstration of the antibodies in the body fluids of syphilitis. This method depends on the principle of hemolysis and is too complicated for the limits of this abstract. The authors were able to determine with almost positive certainty in a large number of cases the existence of syphilis in an individual, irrespective of the length of time since infection. The luetic reaction is most intense in the untreated, and is faint or may even be absent in certain cases that have been well treated and are apparently entirely cured. [R. I. L.]

13. JESIONEK, A. *An Historical Retrospect of the Progress in Medicine in the University of Giessen during the Last Two Hundred Years.*

1. Rolly reviews the clinical manifestations of genito-urinary tuberculosis: in 60% of the cases the first symptoms were referable to the bladder; in 20% the first sign was pain in the region of the kidneys; in 10% hematuria, with or without colicky pain, first drew attention to the condition. The infection may be ascending or descending, probably the former is the most common, *i.e.*, infection of bladder, or of testicle, then bladder and later ureter and kidneys. In every case of genito-urinary disease, in which the etiology is not immediately clear, one should think of tuberculosis. The presence of tuberculosis in this region can be diagnosed, however, only by the demonstration of tubercle bacilli in the urine. Here arises another difficulty, on account of the great similarity between the tubercle bacillus and the acid-fast smegma bacillus. Rolly has carried out a large series of comparative experiments with smegma and tubercle bacilli, and claims that it is impossible to differentiate the one from the other by any known staining reaction, nor are the morphological differences marked enough to warrant a diagnosis. With differentiation by cultures, also, he has had little success. With animal inoculation, however, he has been able, in every case, to differentiate clearly. The smegma bacillus never causes pathologic changes in the guinea pig, whereas the tubercle bacillus always brings about definite lesions. This is, therefore, the means by which a diagnosis of genito-urinary tuberculosis may be definitely made. The author has also examined a large number of advanced phthisis patients, without genito-urinary tuberculosis, without ever being able to demonstrate tubercle bacilli in the urine.

3. Seel reviews the chemistry of the combinations of phenol with the potassium phenol salts, as well as those of cresol with potassium cresol salts. They are not simple phenolates nor cresolates, but a double combination of three molecules of phenol (or cresol) with one molecule of potassium phenolate (or cresolate). The bactericidal power of these combinations is the same as that of phenol or cresol. The main advantage lies in the crystalline form, which makes it possible to use them in tablets of known strength.

6. Loehlein reports the case of a man of fifty-eight, with advanced chronic contracted kidneys. At autopsy an abscess, unsuspected before death, was found in the right temporal lobe of the brain. It contained thick greenish-yellow pus. Over it the pia was injected, but no exudate was demonstrable; deeper in the temporal lobe a second smaller focus similar to the first was found. Examination of the pus revealed the presence of large numbers of streptothrix, which in cultures and animal inoculation showed all the characteristics of the streptothrix Eppingeri, described by Eppinger in connection with abscess of the brain. The most careful examination showed no source of infection, either from ear, lungs or elsewhere; the abscess was apparently primary in the brain substance. [R. D.]

6. *MOSES, F. *The Present Position of the Atoxyl Treatment of Syphilis.*

1. Placzek and Krause give the clinical history and operation findings of a most interesting case. The patient, a woman of twenty-five, with good family and previous history, began to suffer from vomiting and unsteadiness in gait. When seen she complained of headache, double vision, dizziness and repeated vomiting. There was a complete paralysis of the right facial nerve, without reaction of degeneration; slight ptosis of left eyelid was noted. The movements of the right eye were lost but for a slight movement upward and downward. The left eye could only be moved very slightly outward, and a slight nystagmus was also present on this side. Retinæ were normal, also optic nerves were both normal. The gait was staggering, the patient falling now and then to the left side. Standing with eyes open, the patient swayed to a marked degree. On these findings a diagnosis of tumor in the posterior fossa was made. Against actual cerebellar tumor was the absence of optic neuritis, and of stiffness of the neck. At operation, towards the median line, below the cerebellar hemisphere, was found a tense bladder-like cyst, the walls of which were composed of normal arachnoidea. The cyst was emptied of a large amount of clear fluid. Puncture of the ventricles gave no increase of fluid. The patient made a long, slow convalescence, complicated by sudden and severe attacks of fever between 103° and 105°, lasting from one to three days, and separated one from the other by afebrile periods of from five days to two weeks, without localizing symptoms of any kind, and without symptoms suggestive of sepsis. These febrile periods disappeared after four months and the patient recovered completely. All other causes of fever having been carefully ruled out, the authors conclude that in this case the febrile periods were of cerebral origin and due to the manipulation of the region of the medulla, necessary at the operation.

2. Peiser recognizes three forms of habitual vomiting in infants. The first occurs in healthy appearing babies who receive too much food at one feeding, or are fed too often, or the milk is too rich in fat. These cases are easily controlled by regulating the amount and the number of feedings, or by cutting down the fats. A second form occurs in children who though apparently well nourished are of nervous temperament, awake easily, cry much and are easily irritated. Here the vomiting occurs from two to four hours after feeding, when normally the stomach should be empty. Often in this class of cases laryngismus stridulus or tetany occurs. In certain families with marked neurasthenic tendency, all the children are subject to this form of habitual vomiting, which is extremely resistant to treatment and finally disappears spontaneously. The author considers this form to be due to a pyloric spasm, more easily excited in such highly strung children.

The third form occurs in badly nourished weak infants, and is more a regurgitation than an actual vomiting. In observations on such children with the x-ray, the stomach was dilated and the period of gastric digestion prolonged. The vomiting in this latter class of cases takes place three or four hours after feeding. The cause is probably a weakness of the musculature of the stomach and particularly of the cardiac orifice, which allows of a regurgitation of food. The treatment of this third form is general, and not until the general condition of the child is normal will the regurgitation disappear.

6. Moses reviews the success of the treatment of syphilis by atoxyl as published up to date. With but few exceptions each observer has been able to report certain cases of syphilis which have done well under atoxyl, but the consensus of opinion is that its efficiency is not nearly so high as that of mercury and iodides. In a series of 19 cases of syphilis treated with atoxyl by the author 5 were cured, and 7 improved greatly under the treatment. Toxic symptoms referable to atoxyl were diarrhea in 7, albumin in the urine in 3, albumin with casts in 1 case. Disturbances of sight were noticed in none of the cases. The injections were accompanied by no local reaction, and were painless. Moses concludes that in all cases where for any reason mercury cannot be borne or is contra-indicated, atoxyl should be tried. The dosage should be carefully regulated, never more than 3.5 gm. (gr. lii) in all. Atoxyl is by no means so harmless a drug as has been claimed.

2. The weightiest factor in gout is the "uricemia," first noted by Garrod. The source of the uric acid in the body is the purin bases, derived in turn from the breaking up of nuclein and nucleic acid by the action of ferments. In man the source of uric acid in the urine is twofold: (1) endogenous, from the breaking down of the nuclei of cells in the body and (2) exogenous, from the diet. The question of uric acid content of the blood also depends upon the above factors, and it has been found in a series of observations on patients with gout, who were kept for months on a purin-free diet, that there was a constant though small amount of uric acid in the blood. From this it is fair to suppose that in gout there is a disturbance of endogenous uric acid metabolism as well as of the exogenous. Three possible causes of increased uric acid content of the blood are: (1) diminished excretion, (2) diminished uricolysis, (3) increased uric acid production. The authors find that the real factors are a diminished uricolysis through diminished fermentative action. They find also an increase in the excretory period for exogenous uric acid; in other words, we have an anomalous condition of the entire nuclein metabolism. In a gouty person, the increase of nucleins in the diet will precipitate an acute attack. It has been found that the addition of HCl to a saturated watery solution of uric acid will lower the solubility, and sodium salts have the same effect on a saturated watery solution of monosodium urate. Working along these lines Loghem injected uric acid, subcutaneously, into rabbits, and found that the deposit of urates in the tissue could be prevented by large doses of HCl, which lowered the sodium content of the body fluids. By giving sodium bicarbonate, instead of HCl, the deposit was hastened and increased. Other observers have carried out the same experiments with like results. These observations show that the early alkali treatment of gout was of no value, and probably increased the severity of the attack, and also that Falkenstein's empirical observation that gouty persons improved under the use of HCl had a physiological basis. The authors consider HCl of greatest value in the treatment of gout. As in diabetes the metabolism of sugars is upset, so in gout the nuclein metabolism is impaired. We must therefore regulate the diet, so that it shall be purin-free, and continue so over long periods, to be regulated by the severity and frequency of the acute attacks. This does not mean a pure vegetable diet, by any means, as the alkali of the vegetables will precipitate acute attacks. First in importance in the diet of gout, are carbohydrates, in the form of cereals, and then fats. Albumin is allowed, so long it is not meat albumin. Vegetables and fruits should be given with care. The diet must not be too rich in salt. The patient should receive 20 or 30 drops of dilute HCl three times a day. Much exercise is to be recommended, as it has been shown that exercise has a direct effect on the nuclein metabolism. The authors have seen no good results in "washing out" the uric acid with alkaline waters; also little can be said in favor of the drugs which are given as solvents of uric acid (piperazin, etc.). The drinking of large quantities of plain water is to be recommended. It must be remembered that régime in all things is as important in gout as in diabetes and nephritis.

12. The possibility of the existence of an intermittent fever, in form entirely similar to that of malaria, but the result of visceral syphilis, is but little recognized and the

condition is one that might readily escape diagnosis, and, what is more important, fail to get appropriate therapy. Mannaberg reports several of these cases, which under treatment with mercury and iodide rapidly recovered, with decrease in size of the liver.

13. Kobler has observed cases which present a picture suggestive of Asiatic cholera, with marked gastric and intestinal disturbances, in which examination of the blood reveals a malarial infection. Quinine cures these cases. In regions where cholera is to be expected, such cases may be incorrectly diagnosed as cholera and a useless quarantine be established. Consequently, the possibility of malaria with intestinal manifestations is to be borne in mind.

19. The more exact hematologic studies of recent years have revealed many cases presenting variations from the common types. Helly believes such cases should be reported in detail, in order that later data may be at hand for a proper classification of the blood diseases. At present a satisfactory grouping is not possible. He describes a case presenting many of the characteristics of pernicious anemia, combined with those of cirrhosis of the liver. A peculiarity of the post-mortem findings was the occurrence in the bone marrow of many foci composed of cells resembling lymphocytes. [The reviewer believes it is important to record such cases, but more minute hematologic study during life than was given these cases is necessary before such data will be of much aid in making a final satisfactory classification.]

20. According to Leiner, in infants the kidneys can be paipated very frequently, especially if there is emaciation, and often the kidneys are slightly movable. Such, however, is not to be regarded as a pathological condition. A true wandering kidney (a pathological condition) is very rare in infants.

22. See "Progress in Theory and Practice of Medicine"; blood pressure, Boston Medical and Surgical Journal, 1907, clvii, p. 222.)

23. See same.

24. An understanding of cardiac arrythmia has received great assistance from the graphic method of simultaneously studying the radial pulse, cardiac impulse and venous pulsations by means of tracings made with receiving and recording tambours. In many cases, however, there is no palpable apex impulse or visible venous pulsation in the neck. In such cases Minkowski has given us a method which consists of a graphic record of the pulsations of the left auricle, made by means of a stomach tube in the esophagus. The pulsations of the left auricle are transmitted through the anterior wall of the esophagus. With an inflated membrane in the esophagus connected with the opening in a stomach tube, such pulsations can be transmitted and recorded on a revolving drum. These can be compared with ventricular pulsations recorded at the apex, or in peripheral arteries. The present paper, by means of several cases, shows the applicability and usefulness of the method. Also its limitations are touched upon.

28. Weismayr describes a case of pulmonary tuberculosis, in whose sputum there were thread-like and branching forms of tubercle bacilli during a period of eight days. Many other examinations during a period of two years showed only the ordinary forms. Pleomorphic forms occur in old cultures and under certain artificial conditions, but they are uncommon in sputum.

30. A case report. The squamous cell carcinoma was confined to the mucosa of the gall bladder. The sarcoma was of the myosarcoma type and metastasized in the liver. In the metastases there were osteoid areas.

32. A report of two cases with a careful study of the changes produced in the structure of the ear.

34. The most remarkable thing about this case, reported by Weiss, is the very great extent of lung whose blood supply had been gradually cut off by thrombosis, without producing any very severe symptoms. The diagnostic point of most importance in obstruction of pulmonary arteries is the sudden appearance of a systolic murmur heard in the second and third interspaces near the sternal margin and accompanied by clear valvular heart sounds.

36. H. v. Schrötter gives a very careful clinical and pathological study of a case of bronchial carcinoma. In the former he emphasizes the importance of bronchoscopy and x-ray examination as means of accurate early diagnosis. The tumor in this case he believes to have originated in a large bronchus and extended into the lung. The cells were particularly rich in glycogen. The tumor was of the flat cell type. [H. A. C.]

4. Pichon, R. *Hernia of Muscles.* (*Myocèles.*) (Continued article.)
5. *Baumgartner, A., and Huquier, A. *Subastragaloid Dislocation of the Foot.*

3. Mally calls attention to the great success of the Finsen light in the treatment of lupus. He does not agree with the view, however, which explains this therapeutic action by assuming a bactericidal power for the light. On the contrary, he feels that we have here to do with a counterirritant, acting in the same way as scarification, or the application of chemicals, but having the remarkable quality of causing neither pain nor intolerance. The great value of phototherapy lies in the fact that it is painless. Cases of lupus should be exposed daily, for an hour or more, to the action of the light, over a period of about five or six months. This is followed by a suspension of all treatments for about the same period, at the end of which they are resumed. The average case is cured at the end of this second period of treatment.

5. Subastragaloid dislocation of the foot, if recent and uncomplicated, should be reduced immediately after the accident. Lateral dislocations are reduced by abduction for internal dislocation, or adduction for external, at the same time pushing the head of the astragalus backward. A second form of lateral dislocation can only be reduced after having first placed the foot in forced flexion on the leg. Antero-posterior dislocations are to be reduced by downward traction of the foot as a whole, in the long axis of the leg, followed by pushing the foot either forward or backward. Recent irreducible dislocations, without external wound, should be treated by arthrotomy and removal of whatever hinders reduction. It may be necessary to remove the head of the astragalus before reposition of the body of the bone can be accomplished. Occasionally, even this does not suffice, in which case the astragalus must be removed as a whole. Compound, infected dislocations should be immediately treated by astragalectomy and drainage. The authors give the results of 23 astragalectomies as follows: (1) Good functional result in 13; (2) ankylosis in 6; (3) secondary amputation in 1; (4) death from infection in 2; and (5) one case untraced.

[W. C. Q.]

Miscellany.

THE MASSACHUSETTS MEDICAL SOCIETY.

MEETING OF THE COUNCIL.

A stated meeting of the Council was held in the Medical Library, Boston, on Wednesday, Oct. 2, 1907.

The meeting was called to order at 12 noon by the president, Dr. G. W. Gay. Eighty councilors were present.

Delegates to the meetings of other state medical societies were appointed as follows: Vermont, Drs. C. K. Cutter, of Somerville, H. G. Stetson, of Greenfield; New York, Drs. H. F. Vickery, of Boston, Henry Colt, of Pittsfield.

On motion of Dr. Wheatley it was voted that

a committee of three, of which the president of the society shall be one, be appointed to consider and report at the next meeting of the Council what action, if any, it will recommend the Society to take in regard to defending its members in suits for malpractice.

The following were appointed to constitute the committee: Drs. G. W. Gay, F. G. Wheatley, C. H. Cook.

Attention was called to the request of the American Medical Association that the Society take action regarding the establishment of branch associations of the American Medical Association, the North Atlantic branch to consist of the State Medical societies of the New England states and of New York and New Jersey.

Voted, to refer the matter to the Committee on State and National Legislation to report thereon at the next meeting of the Council.

Correspondence.

LETTER FROM PARIS.

[From our Special Correspondent.]

RECENT PAPERS FROM PROFESSOR CHANTEMESSE..

PARIS, Sept. 13, 1907.

Mr. Editor: The early summer months were marked this year in Paris by the appearance of an unusual series of interesting medical papers, of which I shall endeavor to give you the gist in these fall letters.

The most important one, Calmette's ophthalmo-reaction to tuberculin, I dealt with in my letter of a fortnight ago. To-day I shall consider two communications from Professor Chantemesse, one of the less-known members of the Paris Faculty, but a hard worker for all that. As one of these papers is a direct outcome of Calmette's experiments, we can suitably take it up first.

THE OPHTHALMO-REACTION TO THE TYPHOID TOXIN.

Chantemesse, as you probably have heard, is the author of a serum for the treatment of typhoid fever. This serum he has now employed for a number of years, and according to a statistical table published in 1904, it has in his hands given the following results: Whereas during a period of four and three quarters years in the fourteen largest general hospitals of Paris there were 3,595 cases of typhoid fever, with 753 deaths, an average rate of 17.3%, in Chantemesse's wards and for the same length of time (April 1, 1901, to Jan. 1, 1906) there were 712 cases, with 27 deaths, an average rate of 3.7%. This is a truly remarkable showing, when we bear in mind the length of the period it concerns, the fact that these are hospital patients and the efficiency of the Paris hospital nurse.

But there appears to be something mysterious about this serum, which would seem to be confined to the practice of Chantemesse and about three other physicians. If it really is efficacious, and certainly these figures indicate that it is, how comes it that the serum is not prepared for the profession at large and used by them, in so common and serious a disorder as typhoid fever?

Well, Chantemesse has been trying to adapt the ophthalmo-reaction method to typhoid fever, and the idea is an interesting one and may lead to developments. It is self-evident that in importance it is not to be mentioned in the same day with Calmette's affair, the early and visible diagnosis of a case of typhoid not being often a matter of any great moment — you have only to wait and you will find out all right! Still, curiously enough, it might be of considerable use to us physicians whose practice consists of traveling Americans. We are frequently called on to see patients just sailing for home, but presenting a doubtful condition, — headache, slight rise of temperature, furred tongue and constipation, a state of affairs having existed already for several days. The question that then arises is whether the case is merely one due to much traveling and will yield to starvation and laxatives, or whether it is one of incipient typhoid, and the patient ought to be advised to give up sailing by a certain steamer, often a serious matter, especially at this time of year. In such instances a means of early diagnosis, otherwise I believe impossible, would unquestionably be of value.

Anyhow, Chantemesse proceeds just as Calmette does. He takes a strong solution of typhoid toxin, precipitates it by means of pure alcohol, and obtains a powder, which, at the dose of 1-50 mgm., dissolved in a drop of water and instilled in the eye, gives in suitable cases an ophthalmo-reaction just like Calmette's, and with all its characters, — rapidity, harmlessness, brief redness when no typhoid is present, more serious and prolonged reaction in positive cases, etc. The only troublesome point will be how to have the preparation always at our disposal!

However interesting these facts may be on purely scientific grounds, and as an example of what may prove to be a general law of pathology, it is difficult to believe that the method is destined to turn out to be of much value to the practising physician, unless in very exceptional instances.

ON THE PROPHYLAXIS AND TREATMENT OF PERITONEAL INFECTION AFTER TYPHOID PERFORATION, BY MEANS OF THE HYPERLEUCOCYTOSIS INDUCED BY HYPODERMIC INJECTIONS OF SODIUM NUCLEINATE.

This is the title of Professor Chantemesse's second paper, in which he begins by recalling the fact that the gravest danger to which typhoid patients are exposed is peritonitis following on perforation; the frequency of which accident, in a compilation of about 20,000 cases, he finds to be 2½%.

This complication, when abandoned to itself, is almost invariably fatal. It can only be cured by a surgical intervention, and this intervention must furthermore be immediate. Physicians and surgeons of all countries agree that after a lapse of eight or ten hours from the occurrence of perforation the patient's chance, even from surgery, is hopeless; the perforation can be closed, but the evolution of the peritoneal inflammation, to which it has given rise, will continue to a fatal issue.

The problem then is to diagnose perforation as soon as it occurs; are there signs that render this possible?

Going over the symptoms that have been described, Chantemesse observes that none of them is at all characteristic of actual perforation; they are all dependent on the peritoneal reaction the perforation has occasioned, and, as mentioned above, when peritoneal infection has once got under way, the time for intervention is past. In addition to this, the symptoms of peritoneal reaction may also be due to peritonitis by propagation, without perforation; or, they may either be very slight or be altogether wanting, at the early stage of a very small perforation.

The quandary then of the practitioner and his moral responsibility are very great; imperative necessity for certainty in diagnosis, a serious surgical intervention being the outcome; and no means of attaining this end!

In presence of this grave *impasse* Chantemesse has made an interesting attempt to at least improve the situation *by increasing the patient's power of resistance to peritoneal infection;* and he raises the question whether we may not be able to prevent, check, or at least moderate this peritoneal inflammation, to oblige it to develop less rapidly, to put the patient in a better posture against it, and to bring about a state of affairs such that the surgeon on opening the abdomen will find the serous membrane in a condition of vigorous defensive reaction.

Typhoid intestinal perforation, left to itself, carries off the patient in from two to five days; Chantemesse thinks that by inducing hyperleucocytosis in the blood and peritoneum by means of hypodermic injections of sodium nucleinate, the patient's resistance to peritoneal infection may be made to extend over a period of *ten* days or more, so as possibly, in some few cases, to admit of spontaneous recovery when the perforation is small and placed in such a way as to allow the omentum to obliterate it.

The human system defends itself against the invasion of germs by the natural function known as phagocytosis;

it is very probable that a number of remedies, whose efficacy has stood the test of time, such as quinine in malaria, antitoxin in diphtheria, collargol in pneumonia, act largely by the hyperleucocytosis they induce.

Now there is among the therapeutic agents that produce hyperleucocytosis, one, nuclein, that has attracted Chantemesse's attention, and which he has employed in sterile hypodermic injections of a 1% solution in artificial serum. Six to eight hours after such an injection, hyperleucocytosis of a mononuclear type is observed; this increases during about forty-eight hours, and then gradually disappears in four or five days. The increase in white globules is very considerable, their number doubling, or even more.

When a dose of 1 cg. is injected *into the vein* of an arm, the patient feels in two or three hours slight rigors, soon followed by a rise of temperature to 104°. This aseptic pyrexia, a defensive process, is of short duration, is accompanied by very manifest leucocytosis, and ends in the space of a few hours.

The preferable way of giving the remedy is *subcutaneously*. Forty centigrams of sodium nucleinate dissolved in 40 cc. of sterile normal saline solution and administered in one or two injections beneath the skin of the abdomen or external aspect of the thigh, produce in a few hours a slight degree of local pain. In twenty-four hours the region sometimes swells slightly and reddens, which signs all disappear in another twenty-four hours. Two or three days later a second injection can be given, and again a third, lessening the dose each time; hyperleucocytosis is in this way maintained and favors the system in the struggle in which it is engaged.

The opsonic index, or stimulating power of the patient's serum as regards his leucocytes, can be measured before and after each injection. In a case of intestinal perforation treated by sodium nucleinate, Chantemesse made this calculation, and found that in twenty-four hours the opsonic index passed from 1.60 to 2.50, while the peritoneal inflammation was found to have manifestly receded.

From a clinical point of view, here are the results of Chantemesse's observations: he has had several typhoid patients who, after intestinal hemorrhage, experienced severe pain in the abdomen, with reaction, muscular defense and disappearance of liver dullness. An injection of nucleinate, given as soon as possible after the appearance of pain, removed it almost completely in twenty-four hours; the day after the injection the abdomen was puffed up, but not painful, resisted palpation, and in some cases conveyed the impression of swollen and immobilized intestinal loops, as is seen in tubercular peritonitis. By repeating the nucleinate injections two or three days later, the peritoneal symptoms all gradually disappeared.

It is, of course, venturesome to claim that these were cases of small intestinal perforation. Still, the following instances that ended fatally seem to throw considerable light on the question.

In two cases, with large intestinal perforation seen at post-mortem, the patients who were not operated on lived *twelve days* after the perforation occurred, thanks to two or three nucleinate injections. And even in these cases the injections were not made at the beginning, but fifteen to eighteen hours later, when the classical signs of peritonitis by perforation were already present. Twenty-four hours after the injections, the patient's situation had noticeably improved to such an extent than an operation could have been undertaken with hopes of success; but this they declined. And when they died, at the end of twelve days, from slow peritonitis, having produced abdominal retraction, the peritoneum was found in a state of systematic defence, the perforations themselves, in spite of their size, being fairly well obliterated by the omentum and organized connective tissue.

By the side of the advantages connected with this powerful therapeutic agent, we must place its drawbacks.

The local pain has been already mentioned. In addition to this the sodium nucleinate puts the system to some strain. It produces in a short time, and in proportion to dose, a rise of temperature and general distress, which although lasting but a few hours, are not specially advantageous to a sick person.

In the case of a healthy person, about to undergo laparotomy the following day, an injection of 40 cg. will prepare the peritoneum admirably for possible operative infection, and without appreciable inconvenience to the patient. This would, however, no longer hold true, if with a very ill patient the operation and injection were to be carried out simultaneously, for then the double shock would be cumulative.

The difference between the action of intravenous injections of collargol in infectious disorders and the hypodermic use of sodium nucleinate appears to be solely one of *degree*, largely in favor of the latter.

The conclusions that Chantemesse has drawn are the following: sodium nucleinate seems to act by a temporary though quite prolonged increase of the phagocytic function; its effects are very marked, and its dose must be adapted to each individual case.

As a preventive it is an energetic remedy against infection. When infection already exists, the nucleinate is useful if applied at the beginning of this complication. Its benefit can be guaged by the degree of defensive reaction it induces, provided the patient be in a state to supply and stand a vigorous reaction.

The hyperleucocytosis it gives rise to is particularly useful in preventing or moderating the evolution of a case of peritonitis starting in the organs covered by that serous membrane, whether spontaneous or surgical. Even if it does not cure acute peritonitis, it increases the chance for a successful outcome to a consecutive surgical intervention.

"SPECTATOR."

TUBERCULOSIS AT THE LONG ISLAND HOSPITAL.

BOSTON, Oct. 6, 1907.

Mr. Editor: In the "Medical Notes" of last week was a statement regarding tuberculosis at Long Island Hospital, with a call on the trustees of the Consumptives' Hospital to do something to relieve the congestion there.

It seemed in reading the Note as though your reporter must have written the same in a hurry, and without much consideration of the facts in the case.

There is, consequent to the campaign of education that has been going on for years, a decided demand for beds in which tubercular patients may be cared for, but outside of the Long Island Hospital, the city has only been able to provide a few additional beds, mostly in the Holy Ghost Hospital in Cambridge. The trustees of the new Consumptives' Hospital are working as rapidly as possible to get their building started. But under the existing economic conditions they will be able to provide only a small part of the needed beds, and that not at once. Certainly, the Board of Trustees of Pauper Institutions must be prepared to care for all poor people presenting themselves, whatever the pathological condition with which they may be suffering. Consequently, it would seem as though a careful consideration of the field would show them that the Long Island Hospital must be prepared to treat in a proper manner many tuberculous patients for a long time to come, and that they must make arrangements so to do. Meantime the other board will doubtless do all in its power to build as large a hospital as possible for tuberculosis patients.

Very respectfully yours,
A. K. STONE, M.D.

[Dr. Stone has apparently read into our notice of tuberculosis at the Long Island Hospital a meaning which it was not our desire to convey. It is true that this hospital is overcrowded with tuberculous patients to the detriment of those suffering from other diseases, and it is no less true that it is desirable for the Consumptives' Hospital trustees to take as early measures as possible to provide for this class of cases unless separate buildings can be provided at Long Island. We recognize perfectly the duty of the Long Island Hopital in respect to tuberculosis, but the fact must not be lost sight of that if tuberculous patients are to be treated there, they must be properly provided for, both in their own interest and in that of patients suffering from other diseases. The present situation is altogether unfortunate. — ED.]

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING OCT. 5, 1907.

L. H. WHEELER, assistant surgeon. Detached from the "Raleigh," when placed out of commission, and ordered home to await orders.

G. L. WICKES, assistant surgeon. Detached from the "Cincinnati," when placed out of commission, and ordered home to await orders.

B. H. DORSEY, passed assistant surgeon. Ordered to the "Washington."

M. K. JOHNSON, surgeon. Detached from the Naval Training Station, Charleston, S. C., and ordered to the Naval Training Station, Newport, R. I.

H. A. DUNN, passed assistant surgeon. Ordered to additional duty with Naval Recruiting Party No. 2.

H. W. COLE, JR., assistant surgeon. Orders to the Naval Training Station, Newport, R. I., revoked; detached from the "Alabama" and ordered to the Naval Training Station, Charleston, S. C., Oct. 6.

A. B. CLIFFORD, assistant surgeon. Ordered to duty at the Naval Medical School Hospital, Washington, D. C.

E. L. JONES, assistant surgeon. Detached from the "Milwaukee" and ordered to the "Maryland."

The following officers have been ordered to the Naval Medical School, Washington, D. C., for course of instruction: Assistant Surgeons A. B. HAYWARD, G. D. HALE and J. T. MILLER.

APPOINTMENTS.

DR. PHILIP COOMBS KNAPP has been appointed Clinical Instructor in Diseases of the Nervous System at the Harvard Medical School for a term of three years.

DR. ROBERT BATTEY GREENOUGH has been appointed Instructor in Surgery at the Harvard Medical School for a term of three years.

DR. H. M. SWIFT has been appointed Assistant Neurologist at the Long Island Hospital, Boston.

SOCIETY NOTICE.

LECTURES BEFORE THE HARVEY SOCIETY, WINTER OF 1907–08.—The program of the Harvey Society course of lectures for the coming year is as follows:

Oct. 26, 1907. Prof. E. O. Jordan, University of Chicago, "The Problems of Sanitation." Nov. 16. Prof. James Ewing, Cornell University, "Etiology of Tumors." Nov. 30. Prof. D. L. Edsall, University of Pennsylvania, "The Bearing of Metabolism Studies on Clinical Medicine." Jan. 11, 1908. Prof. Ernest H. Starling, University of London, "The Chemical Control of the Body." Jan. 25. Prof. George W. Crile, Western Reserve University, "Shock." Feb. 8. Prof. Joseph Jastrow, University of Wisconsin, "Subconsciousness." Feb. 22. Prof. Otto Folin, Harvard University, "Problems of Chemistry in Hospital Practice." March 7. Prof. Ross G. Harrison, Yale University, "Embryonic Transplantation and the Development of the Nervous System." April 11. Prof. E. A. Schäfer, University of Edinburgh, "Artificial Respiration in Man." The lectures are given under the patronage of the New York Academy of Medicine and are held at the Academy Building, 17 West 43d Street, on Saturday evenings at 8.30 o'clock. They are intended for the medical profession and all interested are cordially invited to attend them.

RECENT DEATH.

ALFRED HENRY GOULD, M.D., M.M.S.S., died in Boston, Oct. 2, 1907, aged thirty-four years.

BOOKS AND PAMPHLETS RECEIVED.

Trypanosomes and Trypanosomiases. By A. Laveran and F. Mesnil. Translated and much enlarged by David Nabarro, M.D., B.Sc., D.P.H., London. Illustrated. Chicago: W. T. Keener & Co. 1907.

A Directory of the Charitable and Beneficent Organizations of Boston, together with Legal Suggestions, Laws Applying to Dwellings, etc. Compiled by The Associated Charities of Boston. Fifth edition. Boston: The Old Corner Bookstore, Inc. 1907.

Year Book of the Medical Association of the Greater City of New York. 1907.

University of California Publications in Physiology. The Chemical Character of the Process of Fertilization and Its Bearing upon the Theory of Life Phenomena. By Jacques Loeb.

How to Cure Spleens for Food. By Edward T. Williams, M.D.

Harmful Involution of the Appendix. By Robert T. Morris, M.D. Reprint.

Heart Clots in Pneumonia. By Beverley Robinson, M.D. Reprint.

United States Department of Agriculture. Bureau of Plant Industry. Bulletin No. 112. The Use of Suprarenal Glands in the Physiological Testing of Drug Plants. By Albert C. Crawford. Washington. 1907.

Practical Diagnosis. The Use of Symptoms and Physical Signs in the Diagnosis of Disease. By Hobart Amory Hare, M.D., B.Sc. Sixth edition, revised and enlarged. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1907.

Fiske Fund Prize Dissertation. No. L. Diet in Typhoid Fever. By John Benjamin Nichols, M.D.

Ueber das spizifisch Menschliche in anatomischer, physiologischer und pathologischer Beziehung. Von Dr. Ludwig Hopf. Stuttgart: Fritz Lehmann. 1907.

Obstetrics. A Text-Book for the Use of Students and Practitioners. By J. Whitridge Williams. Second enlarged and revised edition. Illustrated. New York and London: D. Appleton & Co. 1907.

Diseases of the Genito-urinary Organs and the Kidneys. By Robert Holmes Greene, A.M., M.D., and Harlow Brooks, M.D. Illustrated. Philadelphia and London: W. B. Saunders Co. 1907.

The Differentiation of Black Pigment Found in the Liver, Spleen and Kidneys from Coal Dust or Other Foreign Deposits. By Frederick Gaertner, A.M., M.D., LL.D. Reprint.

The Hand of Iron in the Glove of Rubber. By Robert T. Morris, M.D. Reprint.

Address.

THE PRESIDENT'S ADDRESS TO THE SIXTH INTERNATIONAL DERMATOLOGICAL CONGRESS HELD IN NEW YORK, SEPT. 9–14, 1907.

BY JAMES C. WHITE, M.D., BOSTON,
Professor of Dermatology, Emeritus, Harvard University.

My Colleagues from far and near: It is my high duty and privilege to greet you in assembly, to welcome you to this Sixth International Congress of Dermatology, and to all of you, my countrymen and residents of other lands, who had share in placing me in this most honorable office, to offer my sincere thanks.

Many of you are passing through novel experiences; you have been living on the vast tracts of ocean, and have learned how small a part of the world are the spots of earth you call home. You have come to a new and younger land and may be expecting to find much that is strange to you. If you travel far over our vast continent you will indeed see a great diversity in its peoples, immense inland seas, rivers which in size dwarf your own to brooks, enormous chains of towering mountain peaks, lofty cataracts and deep cañons, marvellous basins and geysers, and magnificent forests of ancient and gigantic trees, overtopping even our heaven-aspiring, Babel-like edifices. We trust you will visit them all. But in your friends and colleagues who stand here on the edge of this new world to meet you with open arms and warm hearts, and who will try to make you feel that this magnificent city is another home to you, you will find nothing novel or strange. We are just as yourselves. In no other land could a great congress be held where visitors would find so close a tie of blood kinship in their hosts.

You Germans and Austria-Hungarians will see right around you more of your race than in almost any city of the Fatherland. You from Holland will find in this town they founded representatives of your oldest and purest families still. You Latins will read the names and hear the tongues which will make certain districts seem as if you were at home again. You Frenchmen may live here as in France, eat the dishes of your best chefs, see such masterpieces of modern French art as you will scarcely find at home, and associate with the best old Gallic stock in our many Huguenot families; and in one of our states, founded by your enterprising ancestors, your old names, your old customs still flourishing. And you of the North, repeating the Viking's earliest voyage to the West, will find in our central regions three mighty states, called New Scandinavia, with an imported but dwindling remnant of your old enemy, Lepra. As for you of Great Britain, are not you and we mostly of one and the same motherhood? Shakespeare and Bacon, Alfred and Elizabeth, and hosts of other illustrious names are as much our ancestors and those of our near and dear sister Canada as they are yours, and far more speak here the common mother-tongue than on your own soil.

Here, then, and in the American part of this congress, you will all find representatives of your own nationalities. Moreover, in some of us the solution of that interesting question in ethnology, — What is the outcome of a mixture of these leading races of mankind?

And no doubt some of you have been wondering on your way hither, what sort of physicians, what sort of dermatologists, shall we find in these men of the Western Continent? Some of you, 'tis true, have met some of us in Europe and have, no doubt, read some of our writings; but all of you do not know all of us in this way, and you perhaps do not know us and our literature as well or as generally as we know you and yours. It is one of the most important functions of this international league to promote our mutual acquaintance. Now there are no great differences between us, you will find. I have just alluded to the identity or similarity of stock. How has professional training affected it? I need not speak of our common schools or of the academic departments of our universities. I grant that yours may be a little more thorough, as the influences of ours are more generally diffused. The period of required professional study is longer with you than it has hitherto been with us, but now the best educated young men amongst us do not obtain their degree of Doctor of Medicine before they are twenty-six or twenty-seven years old; and after that may come further study in European schools. We may all alike read the works of the great masters in medicine of all nations. We have at home only too many medical schools; we have one hundred and twenty-five professors and teachers of dermatology. We have large and well equipped special laboratories and clinics, perhaps the largest and most magnificent medical school building in the world, and we have produced some admirable and exhaustive treatises and countless papers on dermatology. Most of our teachers have had the advantage of studying our subject with the most distinguished teachers of Europe, living and dead. You see, therefore, that you should find us very much the same as yourselves, and that we meet as equals, alike prepared to study and discuss the questions and cases which shall be presented for our consideration, and equally desirous of contributing to the advance of our department of medicine. In one point we may indeed find ourselves your inferiors: in our efforts to repay in the same measure the grand hospitality you have so often shown us. But this failure shall not come from any lack of desire or effort on our part.

Permit me to offer you a brief sketch of some of the changes which have taken place in the study and practice of dermatology under the observation of the oldest student among you in the last half century. In 1856 and 1857 I sat in the clinic of Ferdinand Hebra in Vienna, that marvellous training school of future dermatologists. I took with me to Europe a clean slate, for at that time no instruction in skin diseases worth mentioning was given in America, therefore, that terribly iconoclastic feature of his teaching was needless

for his transatlantic hearers. It seemed to me then that this ticket admitted me to an almost perfect system of object-lesson instruction, given by a master of keenest observation, of merciless invective toward the schoolmen of the past, of enthusiasm-inspiring earnestness. No one could fail of learning a great deal under such teaching. I still believe it deserved and still deserves the title unparalleled. We were taught to observe closely what we saw, and to waste no time in attempting to classify the result of such observation under undemonstrable etiological or pathological theories; moreover, to treat lesions by remedies addressed as immediately as possible to them and not to imaginary causes. Treatment, therefore, was purely empirical. We did try to look a little below the surface of the skin, and a limited number of parasitic affections were then recognized. We did take portions of diseased cutaneous tissue, and under Professor Wedl's directions tease them out into shreds under the microscope. We had not then arrived at the knowledge of infinitely attenuated section-cutting, of chemical reactions beyond the solvent power of potash, or of the innumerable, discriminating stains of to-day. No wonder, then, that we failed to recognize the all-present foreign organisms beneath our very eyes. At that period the school of Vienna was at its highest mark, and under such men as Skoda, Rokitansky, Oppolzer, Hyrtle and Sigmund, one had unsurpassed advantages of instruction in other branches of medicine.

Paris was then beginning to lose that supremacy she had so long held undisputed as Vienna rose. There Hardy was giving excellent instruction. Bazin was possessed by his overmastering theories of dartrism, arthritism and the like, and Ricord still reigned as the unrivalled teacher in syphilis. Wilson, with his fluctuating views on etiology and nomenclature, was the sole authority in English-speaking countries. Simon was in Berlin, Veiel, Sen., in Canstatt, Boeck, Sen., in Christiania, and Fuchs had just died in Göttingen. These were our worthy predecessors in dermatology fifty years ago. There were but few professorships and clinics, and no special laboratories. The literature of our subject was scanty. Hebra had as yet published no book but his surpassing Atlas, and there were no journals devoted exclusively to the interests of our department.

In America dermatology was scarcely recognized as a specialty. No systematized instruction in it was given in any school of medicine. There were no special clinics connected with them, and in our hospitals no wards for the treatment of skin diseases. There was hardly a physician exclusively engaged in the practice of this class of affections. All these opportunities for the study and teaching of dermatology had to be created. It has been a long and hard struggle to overcome the opposition on the part of the general profession, the governing boards of hospitals, and the faculties of our medical schools to the position of dermatology as an independent department of medicine. One obstacle has been the unfortunate fact that the universities had no hospitals under their control, no clinical material to offer their appointees. Then, too, our National Government has no share in the direction either of universities or hospitals, so as to regulate or unify medical education. Therefore, this struggle for recognition on the part of your colleagues in the United States had to be made single-handed in every hospital and every institution for medical education. It is not quite yet wholly over, but we may rejoice in great advances. Nearly every one of our one hundred and sixty or more schools of medicine gives special instruction in dermatology, most of our large hospitals make at least provision for out-patients with skin diseases, a few of them have wards for their exclusive care, and all our cities and towns of magnitude have practitioners of this specialty. We have a National Dermatological Association, now thirty years old and numbering sixty associates, a large Dermatological Section in the American Medical Association, and many of our most important cities have local dermatological clubs or societies, all of whose proceedings are published. Then, too, we have long had (under various titles) an *American Journal of Cutaneous Diseases*. There have been published also extensive treatises, cyclopedias, atlases and monographs by American workers. You see, therefore, that we do not stand so far below the standard of activity you, our colleagues from abroad more favored in opportunities, have set for us.

The attention of our American school was first directed to determine what differences might exist between dermatoses here and in Europe, how far, that is, they might vary on account of diversities in climate, racial stock, methods of living, morals, dietaries, etc. For this purpose a careful collection of statistics has been made by members of the American Dermatological Association representing observations made in all parts of the United States and Canada. The number of cases thus collated amounts to more than half a million. Their value is exceptionally great and reliable, because they are founded upon the observation of trained dermatologists. A study of them reveals some striking features: the almost complete absence of some affections common in Europe, the occurrence here of others only by direct importation, a variation in the intensity of certain pathological processes, even an inclination to self-extinction in some of them, and the existence here of certain diseases not occurring elsewhere. In recent years our efforts have been especially directed to the foundation of laboratories devoted to research into the essential nature of skin diseases. The results of such investigations are already of high importance and promise.

The recognition of the importance of such researches has completely changed the method of teaching dermatology amongst us. We are no longer content with those of our former great masters, — the didactic lectures in course, a rapid survey of the whole field of cutaneous medicine, with clinical illustrations, it is true, but scanned mostly afar, and at close view only by the

fortunate holders of the first row of seats or by the most successful rushers of the crowd around the bedside. The medical student at our best schools takes up its study after two or three years' laboratory drill in histology, biological chemistry, pathology, bacteriology and all practical methods of microscopy. He comes thus prepared to apply this knowledge to the proper understanding of the wide pathological panorama which skin diseases present. He makes himself familiar with their clinical features by sight, by touch, in sections, or classes of a few members, three to ten only. He sees what the biopsy reveals of anatomical changes, and what bacteriological researches may discover. He must elucidate the history of cases, and give the grounds for the diagnoses he must present. All this study is carried on in the immediate presence of the instructor, who directs and criticises at every step in the clinic and laboratory. Such is the individual system of teaching dermatology to-day with us. For graduate students greater facilities are furnished, work in special laboratories, and the study of great numbers of clinical cases for eight hours of the day throughout the year under the constant supervision of instructors. Such modern methods of teaching cannot fail of yielding a superior product to those of our student days.

With this brief sketch of the evolution of dermatology in North America during a half century we may well note the changes which the same period has brought to pass in our department everywhere. European schools have risen and declined in popularity with the coming and passing of celebrated teachers. The days of narrowing theories and schoolmen have gone forever, let us hope. In their place we have the marvellous revelations of modern chemistry, physics and the microscope, tangible data for the basis of our etiology and pathology. We may now credibly predict what we are about to discover in both these directions when our knowledge of methods shall have advanced a little farther. We see no bounds to the extent of such discovery. In an address delivered thirty years ago I ventured to predict that I should live to behold with my eyes the cause of pulmonary tuberculosis; of its cutaneous forms we had then no suspicion. We now look backwards upon this memorable event. When our great master of cellular pathology was giving some of you his inspiring instruction, who thought that he might some day come to distant and primitive America to see upon a screen, simultaneously with a thousand other observers, the image of a cell a foot in diameter filled with visible organisms of that scourge of mankind, variola? Even our trained imagination cannot bear us forwards to the limit of such revelation.

When I began the study of skin diseases under Professor Hebra there were upon his tabular list of diseases less than one hundred titles. Since then closer clinical observation, advanced knowledge of their anatomical nature, recent investigations into their etiological relations have individualized and multiplied them until they now number more than two hundred. (At the first meeting of this International Congress in Paris, in 1889, a previously unnoticed disease, discovered simultaneously and independently in France and America, was first brought to your attention. Now we are able to show other dermatoses with which some of you are unacquainted.)

Perhaps a word of caution regarding the unnecessary division of diseases and multiplication of titles may not be out of place here. It seems to me that some of us are over-inclined to magnify the significance of slight clinical variations, to attribute to them specific importance, and to emphasize their pseudo-independence by bestowing upon them titles of individuality. In my opinion we should not change well established landmarks except for reasons founded on demonstrable differences in anatomy or etiology. Then, too, the character of modern titles has become a matter worthy our serious consideration. It has become too complex and cumbersome, as has the nomenclature of other departments of natural science. There was a time when naturalists were content with simple generic and specific names; now every flower or bird must have at least three or four individual titles bestowed upon it. Are we not in danger of exceeding even this redundancy? There is evident a disposition to avoid such profuse and exhaustively descriptive nomenclature by calling a newly established dermatosis by the name of its sponsor, as Bazin's disease, Kaposi's disease, etc. Some fifty or such titles might be enumerated. This is an entirely arbitrary system of designating a disease, suggesting nothing descriptive of its nature, or its proper position in any plan of scientific classification. If it continue, a pocket glossary will soon become necessary to every reader of our literature, unless blessed with an exceptional memory. Such titles, like those geographical names given to affections of remote regions, may be admissible until the nature of the disease be fully elucidated; then they should be properly christened and registered. It should be one of the most important functions of this international body to prepare and officially adopt some satisfactory system of classification and nomenclature, to which we should adhere for the common good. I believe the creation of a standing committee of this association to consider the subject in a broad way, on which should be representatives of all our great nations, unprejudiced by past systems of schools or individuals, would result in vast advantage to dermatology. The establishment of such an international code should not be an impossibility. Let us undertake it.

And are there not other matters coming within the bounds of our field of medicine, which we, as the most competent body in existence, should take a more prominent part in than heretofore? Should we not feel it incumbent upon us to assume a more advisory and executive position in relation to sanitary questions of international interest, rather than the merely academic one we have hitherto occupied? Had we conscientiously in-

terpreted our highest functions in this direction, it would scarcely have been necessary to found a special international congress for the study and control of leprosy, of syphilis, and of cutaneous tuberculosis. But even if we have allowed our sphere of usefulness to be thus curtailed there yet remain many important questions for us to act upon. I will mention some of them:

1. What are the influences of race, geographical conditions, climate, national customs, etc., upon the evolution and type of diseases of the skin?

2. What variations does emigration induce in dermatoses?

3. What cutaneous affections should national governments regard as infective, and seek to control by restriction of immigration, by enforced insulation, and similar measures?

4. How far is it practicable and incumbent upon national governments to control the continuance and prevalence of hereditary dermatoses by restriction upon marriage laws?

5. Should not the influence of this body be directed to induce governments to aid in the support of researches bearing upon sanitary questions of national importance?

We must all alike be greatly interested in the investigations which have been recently carried on by our colleagues in certain tropical regions which are of vast importance to dermatology and general medicine. We are fortunate in having before us the great privilege of hearing the results of their researches directly from some of the most eminent of them. Primarily these studies have been undertaken so far from the usual centers of such research, because there only could be found available in sufficient abundance the requisite material. Fortunately, we are not yet differentiated so widely from our simian relatives in the physical character of our tissues, that we do not possess in common the susceptibility to the invasion of certain morbific agencies, which are the cause of some of our most disastrous diseases. As their serious nature inhibits the application of the ordinary methods of experimentation to our fellow men, it is indeed fortunate that we may legitimately use these lowly brethren for such purposes.

With the important studies concerning the nature of the variolous affections made at the same time in Manila by Drs. Brinkerhof and Tyzzer you are acquainted. (Their results are published in the *Journal of Medical Research*, January, 1906, under the title: "Studies upon Experimental Variola and Vaccinia in Quadrumana.") I am happy to announce that Dr. Brinkerhof has accepted the appointment from our National Government of medical director of the establishment for the care of lepers in the Hawaiian Islands, and will devote himself for five or ten years in the laboratory he has established on Molokai to the study of this disease. These researches, unrestricted in scope, conducted by so accomplished an investigator, are of great promise.

And there are not a few other affections of close interest to us of which we see only an occasional immigrant example, which can be properly studied only in their tropical home, and should be there studied by experienced dermatologists. It is evident that such researches cannot be carried on at the personal expense of such investigators, or by any one national government on a sufficiently comprehensive basis. It can be accomplished only by the combined efforts of the medical profession of all nations. Now, fortunately, we have in this association just the right body to carry out this all important work. Such an undertaking on our part should be regarded as one of our most appropriate and essential functions. A large fund should be raised, and the aid of our respective governments should be solicited in behalf of the plan. An international committee, composed partly of members of this body, partly of well-known authorities on tropical diseases in all parts of the world, might be established under our administration, which should raise the means for and superintend such investigations. Think of the vast benefit to medical science if we could send out properly trained investigators to any regions where questions of great interest and grave international importance demanded solution. May I suggest that a committee be appointed at this meeting to consider the subject and to report before the adjournment of the congress?

THE NEW PATHOLOGY.

Looking backwards over my fifty years of study and practice in affections of the skin I am led to ask myself, What are the most prominent marks of progress I have observed, and what the present signs of promise are?

I recognize three distinct eras of advance:

1. In place of the artificial systems of classification based on such narrow lines as similarities in external manifestations, especially in the so-called "primary lesion," a superstitious belief in the existence of purely imaginary influences or diatheses as a foundation of etiology, and a survival of the old doctrines that all dermatoses are necessarily merely surface expressions of internal systemic disorders, and that the cutaneous tissues are denied the possibility of independent pathological modification; in place of such an unscientific status as then prevailed there came about, largely through the powerful teaching of a great master, a proper appreciation of the meaning of external manifestations and a regrouping of the mutual relations of individual affections, the recognition of the pathological independence of cutaneous changes, and a healthful skepticism with regard to undemonstrable creeds; a school based on purely clinical data was inaugurated, an immense step upwards, an emergence above the clouds of superstition and fetishism.

2. Under the analytical spirit infused into all departments of medicine by Virchow, students in dermatology did not long remain satisfied with the old methods of studying the anatomical changes which underly the surface expressions of cutaneous disease, but with the resources of improved technique carried their researches into

the minutest details of tissue modification. Thus was built up a knowledge of cutaneous pathology, by which some sort of scientific classification became possible. It was one of anatomical affinity, of identity of structure in the place of one founded on merely external resemblances. This was, indeed, a great advance, but far from satisfactory. It might show that the tissue changes in lupus and leprosy, for instance, closely resembled each other, but not why they clinically were so far apart. It gave not the slightest clew to their etiological relations.

3. There was revealed to one or two patient investigators through advanced methods of technique the presence in the tissues of these two most important diseases of foreign organisms, which explained all the phenomena we had been so blindly observing. This was the key to the secret of causation which had so long baffled us. I need not dwell upon the all-importance of this discovery, and the constantly increasing development in methods of research to which it has led. It has already taught us a vast deal as to the real nature of cutaneous disease, the means of controlling some of the most dangerous forms of pestilence, and given us the hope of solving the mystery of much or all that yet remains unrevealed to us.

These, then, are the three eras of advance within my experience:

1. The knowledge founded on a more careful study of the external manifestations and unbiased interpretation of clinical phenomena.

2. A deeper knowledge of the minute anatomy of tissue changes in, and a more scientific grouping of, dermatoses.

3. The recognition of the real nature and cause of visible lesions and underlying tissue changes and the essence of disease, — a true system of pathology, — the promise of attainment of the power of prevention, of establishing immunity, of founding a broader system of rational therapeutics.

And how shall we interpret the action of the micro-organisms which have been found in so many cutaneous diseases, or which our justifiable convictions forestall the revelation of their existence in others, to such an extent that the remainder will be the exception to such etiological relations? The effects of the parasitism on cutaneous tissues of our earlier experience was purely local and simply inflammatory in character. The trauma of animal parasites produced a slight degree of superficial dermatitis of the immediate surrounding area, sometimes followed by widespread secondary disturbances in consequence of the pruritus thus excited and subsequent scratching. The then known parasitic flora excited also purely local changes in the skin and appendages of unimportant nature. Neither animal nor vegetable forms gave rise to any constitutional disturbance, or endangered life.

Then came the demonstration of the existence of other forms of parasitic organisms in the tissues of far more serious diseases, the etiological relations of which have been established on irrefragable evidence. The tissue changes produced by their presence, both local and remote, and their influence upon their host are of the gravest character, some of them in fact being the cause of the greatest mortality in mankind and other animals within historic times. How can we account for such deadly influences inherent in such infinitely minute organisms, or for the striking differences in the nature of the manifestations they give rise to, in their periods of incubation, the diversity of tissue changes they cause, their variations in course from a few days to many years? Here are two so-called bacilli of minute size, so like in appearance and reaction under known reagents that they can scarcely be distinguished by the most experienced observers, yet just as the human ovule or the plant germ carries with it the inherent capability of building up from the material furnished it the stately tree with its century changes, or the heroic future of a man, so does the micro-organism of lepra bear within its simple and insignificant form the power of transforming human tissues into the fell shape we know; and so does the other possess the undeveloped power of causing the cutaneous tissues to express the influence of its presence in quite different objective forms, and of adding countless victims to the "great white plague." Some of them, too, have a mysterious power of protection, of bestowing immunization upon their human host.

How shall we, I repeat, explain such manifold and far-reaching powers? Can they be mechanical, in part, at least? When we consider the effect of the smallest particle of foreign inert matter upon human tissues at times, the "spec" in the eye for instance, we cannot deny the possibility of such sort of action, in some measure, at least. Can they be chemical in nature? We have only to recall the influence of organisms but slightly higher in the scale of vegetable life, in producing new and beneficial modifications in organic compounds, — the alcoholic and acetous fermentations, for example; or of the most disastrous nature, as some of the oidia. We may feel assured that they, too, may possess the inherent property of generating products too subtile to be recognized by our limited analytical agents, and well capable of producing all grades of tissue change in their immediate presence, as well as those which express themselves in other ways throughout the whole economy; or is there some other subtler form of influence at work, the nature of which is wholly unrevealed?

To such remotely manifested influences we give the name toxins, a well chosen title, perhaps, but bearing in itself no interpretation of their nature. To such mysterious powers we may attribute the prodromal and evanescent cutaneous manifestations in lepra, and the long delayed surface lesions in tuberculosis we call tuberculides. In the solution of this grave question — the nature of the action of such micro-organisms upon human tissues — we have before us an untrodden field of research. The satisfactory answer may be surely expected, for there is no secret of nature which human intelligence may not eventually comprehend.

THE RESULTS OF OUR KNOWLEDGE OF MODERN CUTANEOUS PATHOLOGY ON PRACTICAL THERAPEUTICS.

Is it not lamentable to confess how loitering has been the advance in practical therapeutics upon our recent progress in the knowledge of cutaneous pathology? We are well nigh as helpless in the control of our gravest, as well as of our most common, dermatoses as we were half a century ago, and our most successful therapeutical measures are as empirical in nature as they have ever been. A few until recently unrecognized physical agencies have been employed, working some good, and evil as well, but we are learning that their beneficent powers have narrow limitations. We have recognized the parasitological nature of more and more affections, but our parasiticides can control only the most superficial of them.

So far, our researches in the portentous realms of immunization have not brought forth such practical results as did the shrewd, unaided observations of that old English country physician, Jenner. Can we predict with certainty the curative results of our prescriptions in any individual case of eczema, or psoriasis, or lichen, or acne, or the other common dermatoses which fill our daily clinics, results which convert our most confiding private patients into doubters of our skill, and give encouragement to the ingenious efforts of the nostrum manufacturers? Have we any power over the pigment producing layer of the cuticle? Can we control the disordered actions of the sweat glands? Who claims ability to cure lupus erythematosus, not the one case, but every case? Have we a surer power over the deeper and graver forms of cutaneous disease than the surgeon's hand of fifty years ago?

Now I am not a pessimist in therapeutics. I know that the skilled dermatologist does a vast amount of good in the relief of human suffering, and is fully as successful in dealing with disease as physicians in other fields of practice. Unfortunately for us the immediate results of treatment are always in view. Still I believe in an honest recognition of our present limitations as one of the steps towards securing greater powers of control in the future. I look forward with assurance to the slow coming of successful and rational methods of cure, of which a few happy glimpses have appeared.

PROGRESS.

Even since the last meeting of this congress in Berlin there has been a noteworthy progress in dermatology, especially in research work. The great activity and general interest in this direction are shown by examination of the current literature in connection with a single question. The discovery of spirocheta pallida, its etiological relations to syphilis, and its revolutionary bearings upon the pathology of this disease, have stimulated the production of several hundred articles from observers in all parts of the world. The transference also of the field of investigation in this and kindred diseases from man to his nearest relatives in the animal creation has led to surprising and most important results. Your committee of organization has selected, therefore, as themes for special consideration such subjects as will enable distinguished workers in these fields of research to present to you the results of their latest investigations and conclusions.

You are all familiar with the self-sacrificing spirit in which our distinguished colleague, Professor Neisser, has devoted himself, time, revenue, comfort, to the study of this most important subject, syphilis. How he transferred the field of his investigations from his clinic and observations upon human patients to the distant tropics and the home of the higher apes. You know the invaluable results of the experiments there made. You have read also in his recent report to the German government the details of this work. He was to have been with us on this occasion to present his latest conclusions from the results thus obtained, but alas, in obedience to the call of that government, which has generously appropriated 100,000 marks for the continuation of these investigations, he has again banished himself, with his devoted wife as co-laborer, to the Orient, and sends us a message of his regret that he cannot be present with us. What an example of clinical experimentation on a grand scale, of noble devotion to science and humanity. Will you, his colleagues from all parts of the world, join in sending him our best congratulations upon his continued good health, and a sincere expression of our high appreciation of his all-important labors?

And I would say a word, too, for those dumb relatives of ours, the anthropoid apes, who show their near affinity to us by their susceptibility to this great curse of mankind. Would they could comprehend our grateful appreciation of their passive sacrifices for humanity.

And I cannot close this brief account of most recent progress without alluding to another therapeutic agency evolved from research work in the field of micro-parasitology, the protective and curative influence of the introduction of the modified essence of disease-producing germs within the economy, which we call opsonism. This subject will also be presented by competent observers.

In the face of such surprising results of research in the past few years how inadequately can the keenest imagination foretell the possible progress of the coming decade.

The marked increase in the number of dermatological societies in all civilized countries, some twenty or more existing at present, and the twenty to thirty journals devoted exclusively to the literature of our specialty bear witness also to the progressive interest shown in dermatology, so that it has become well nigh impossible to keep in touch with such a record. You may be surprised also to learn that the number of invitations to attend this congress, sent only to those especially interested in our department of medicine, is twenty-five hundred.

NECROLOGY.

But, alas, it is my sad duty to make brief mention of those who have hitherto worked with us, and who have left us forever since our last meeting.

Neumann, Barthelemy, Tarnowsky, Haslund, Du Castel, Mauriac, Finsen, Shaudinn, Atkinson, Greenough, Allen, Dron.

Some of them were among our most distinguished colleagues, who had labored long and nobly for science and humanity; others were only at the beginning of their brilliant career, already illuminated by splendid achievements — one of them, Allen, a lamented member of your organization committee. During my professional life some forty conspicuous colleagues in our specialty, some of them the great masters, have died. May I ask you to rise for a moment in respect to their memory?

CONCLUSION.

And now in closing I invite your attention to the full and inviting program which the organization committee has prepared and placed in your hands. They have solicited contributions upon the most important subjects from distinguished dermatologists of all countries, and if we have not met with that degree of generous response from our foreign colleagues we expected, we hope with the aid of those who honor us with their presence to make the congress a success.

Original Articles.

THE PROSTATE FROM THE SURGICAL STANDPOINT.*

BY CHARLES S. BENSON, M.D., HAVERHILL, MASS.

THE literature on the prostate gland is most voluminous. One can find carefully prepared statistical reports; papers proving to the writers' satisfaction the only and best method of operative attack. Others show conclusively that catheter life is the only way to handle these sufferers, until the outraged bladder settles the question in its own way.

For all exhaustive treatises, anatomy, functional physiology, histology and pathology, I refer you to the interesting works of Denver, Young, Willy Meyer, Guiteras, Murphy, Chetwood, Keyes, Watson and a host of others. It is a simple matter to abstract any and all of these writers, but of what avail to you and me, for such would be inferior to the originals which lie within your reach.

My personal operative experience is confined to but few cases, all done by way of the perineal route, and all cured, which fact is of little value considering the small number, for the next few may go the other way.

As an interne, however, I assisted at no small number of prostatectomies, and cared for these afterward. Most were done suprapubically, and I have since been rather prejudiced against this method, for convalescence was stormy and mortality was pyrotechnical, as I look back on the fistulæ, and infections of the prevesical space.

Since this paper was presented in the winter I have added two cases only, one of which is now two weeks in the hospital and apparently doing well. This is my only case operated upon by the suprapubic route, and for the reason that it seemed best to divide the operation into two stages.[1]

With only these few prostatectomies to my credit, it may seem presumptuous to address you, but I crave your indulgence for so doing and further ask your tolerance in that I may make these remarks personal, not abstractive, nor quotative, merely as the subject appears to myself. Suppose, then, we discuss the prostate gland along the following lines:

1. Is the patient with a prostate which is symptomatic, better for being subjected to operation, or should he be advised catheter life as long as possible, followed by ultimate operation when catheter life is no longer possible or endurable?

2. If operation is the desideratum, what then constitute the indications for operation?

3. If not operative, is there any other treatment apart from or combined with catheterization?

4. If operation, what shall be the method of attack?

5, and perhaps this would have better come first, although I question it: What constitutes the symptomatology of hypertrophy of the prostate gland which establishes the diagnosis?

6. Prostatism without hypertrophy of the gland, its causes and treatment; the confusion of this with true hypertrophy of the prostate.

Concerning the first proposition, namely, catheter life or operation, there has been during the past several years a very great diversity of opinion as to the preferable means of procedure, and to-day it is still a very much mooted question although I think surgeons are coming nearer together as to the advisability of the earlier operation.

For my own part, it seems to me after diagnosis is established, that the earlier we operate the better the chance of life, the better the chance of complete symptomatic recovery.

To pursue the old course of using the catheter as long as the patient could be made comfortable by such means, and ultimately operating when the patient's condition had become desperate from cystitis and ascending pyelo-nephritis, is wantonly running up the mortality rate and giving us simply palliative surgery. The fact that in individual work the mortality of all methods of operation is between four and six per cent would seem to me a great argument in favor of the earlier operation, before we have infective complications.

The catheter is of the greatest use in establishing the diagnosis, and every patient should be kept under observation for a few months before deciding upon operative measures; but once the diag-

* Read before The Massachusetts Medical Society, June 11, 1907.

[1] This case died of bronchitis some weeks later, suprapubic wound not entirely closed, but clean and granulating.

nosis is unqualifiedly established, the sooner we operate the better.

When I say diagnosis, I mean more than merely that a patient has hypertrophy of the prostate; I mean that this patient has more than merely nocturnal frequency of micturition. I mean, more especially, that urination is difficult to start, is what we call stuttering and stammering during the act; stops slowly with considerable dribbling and soiling of the clothing, and that the relief which ordinarily comes from emptying of the bladder is not experienced by the sufferer from prostatic hypertrophy.

In other words, to go only a step further, we now use the catheter and establish that the patient has four or more ounces of residual urine after urination.

Now it is perfectly possible for this patient to have this amount of residual urine and not have cystitis. I believe that with these symptoms it is not necessary to subject this patient to years of catheter life in the future, but by operating at this time we can save this inconvenience and also get a symptomatic and actual cure.

In this connection it is only fair to say that there are certain types of cases in which operation is probably the last resort after the case has been considered most deliberately, and yet for the most part I think operation should not be undertaken or considered at all.

I refer especially to those cases coming to the practitioner, who have been so long sufferers from an enlarged prostate with its damming back of the urine, whether or not depending at the present time for their visit completely on catheterization. These patients have an atonic bladder, and operation will not cure or relieve symptomatically this condition. It should be undertaken only when there is actual danger of death, in patients comparatively young and to whom every year of life is of the greatest importance, knowing that although you remove the hypertrophy, you still go on to the end with the catheter, and your operation has been done simply to provide the means of introducing the catheter.

Another class where it seems to me operation is questionable, is in old cases which, at the time of being seen, already possess infected bladder and kidney. By all means, in these cases, I should advise a long treatment by catheter and irrigation, unless the case is so desperate that suprapubic drainage affords quickest relief for the infected condition, if there is any relief at all to be obtained. These last cases can only be judged on their individual merits.

There is no dogmatic position of No operation or Operation. One thing is very certain, however. Any operation which takes more than a few minutes to perform will certainly put your patient on the wrong side of the mortality statistics.

To take up the next topic: The desirability of operation being established, what then are the indications?

It almost seems as though I had answered this question in the preceding paragraphs, but it will do no harm to repeat.

For me, at least, I believe that operation is indicated when, upon rectal examination, we find a pronounced enlargement of the prostate gland. When there is difficulty in starting the urinary stream, and, I might say, difficulty in stopping the same, with or without necessity of using the catheter. In addition to this, the discovery of a few ounces of residual urine. These I think, after proper observation, justify advising the patient to submit to operation and enable the surgeon to hold out the prospect of a cure and to inform the patient that taken at this time the risk is very much lessened.

To take in topics three and six under one head, namely, if the case is not operative, is there any treatment apart or combined with catheterization and the subject of prostatism with hypertrophy?

It is impossible to separate these two for the very reason that the only justification of adopting a treatment other than catheter life or operation in hypertrophy of the prostate gland, is the fact that hypertrophy does not exist; that we do have a condition which I have diagnosed as prostatitis, in which there is a certain amount of irritation and congestion of the gland, without any increase in glandular and connective tissue elements, which in itself gives rise to very similar symptoms of the early stages of hypertrophy. Perhaps, if anything, this condition carries with it more pronounced discomfort than the graver type.

Given, then, prostatism of this nature, what are we to do with it?

If we consider the fact that in the majority of instances this is due to an old gonorrhea, we shall come nearer appreciating the treatment which will be most efficacious. We will massage the prostate gland and use instillations of nitrate of silver, deposited in the membranous and prostate urethra. We will use, I say, instillations, not injections, and I wish you to consider this word instillation as spelled with capital letters. It is only a few drops that should be thrown in, and the strength of the solution should be varied according to the indications arising during the course of treatment.

It is rarely that irrigation of the bladder itself will be called for. I might say it is never called for, except as we may irrigate the whole urethral tract; in the milder type of cases, filling up the bladder only that we may get a second passing of the fluid over the area selected when the bladder is emptied.

Perhaps in this connection it will be well to touch upon the possibility of treatment in cases followed with cystitis, ureteritis and pyelitis.

Kelly, of Baltimore, in examination, at one time practiced washing out the ureters and the pelvis of the kidney through catheters passed clear to the renal pelvis. A few other surgeons have tried this method of procedure but, for the most part, however, have condemned it.

I cannot help believing that it is extremely dangerous, even in the most skillful hands, and certainly it is entirely out of the province of the average practitioner who possesses neither the equipment nor the training to even catheterize

the ureters; consequently, in these severe cases we are practically limited in our treatment to vesical drainage alone.

4. Now if we have decided upon operation, how shall we proceed?

We have practically only three operative procedures before us, namely: Bottini, suprapubic, and the perineal. I purposely leave out what is known as the combined method, as being absolutely useless and dangerous in creating an unnecessary opening.

The Bottini operation has, I think, a place, but the limitations are very strict, and it requires a high amount of technical skill and training. It is adapted only to a very mild degree of hypertrophy, or perhaps I might better say to those cases which do not necessarily possess a true hypertrophy of the prostate, but only a stenosis of the vesical orifice, or what is known as the vesical bar. Its great advantages lie in the fact that generally anesthesia is not needed, that the patients are not confined to bed, or even, but for a short time, to the house, yet it is dangerous. It necessitates, also, conditions which allow of a painstaking and minute cystoscopic examination. For the most part this operation has been again assigned to oblivion and will, I trust, remain there. With very few exceptions, it possessed no merits which are not equalled or surpassed by prostatectomy; its only virtue apparently consisting in adaptability to a very small number of cases wherein general anesthesia is absolutely contra-indicated, and any measure which may give relief is justifiable, short of electing actual operative death.

Certainly, the suprapubic operation has its uses.

Personally, I think that in those cases of badly infected bladders, in which the vital tone is very much lowered, that a suprapubic opening done at first only for drainage, and irrigation of the bladder, to be followed after an interval by an enucleation of the prostate gland through the same opening, is the only proper method of procedure in these cases.

We are told that the large, soft prostates are better removed through a suprapubic opening; that the small fibroid prostates are better removed through the perineal opening. We are told by the advocates of suprapubic operation, that the urethra in part is better preserved by suprapubic operation. Yet on the other hand, within two years that party who popularized the suprapubic operation is now pleading for removal of the prostate gland *en masse*, together with the prostatic urethra, of course thus dropping one of his own arguments for the superiority of the suprapubic operation.

We are told that the operation is quicker and the drainage better by this route. I question very much if the operation is any quicker in uncomplicated cases. I question if drainage is not better or as good where the operation and the drainage are sought for at one and the same time in those cases which permit of doing the operation in one stage; certainly not where we are forced to operate in two stages.

For the perineal route which has been so strongly advocated by Young, it is said that we can see the parts as in any dissection. The same claim is made as for the suprapubic route, that the drainage is better by the perineum. It is further claimed for the perineal operation that we can preserve ejaculatory ducts, and so preserve the potency of the patient. Now as a matter of fact, I reserve for myself the same right in the election of the method of operation as I would reserve for myself if I were practising medicine. If I were an internist and I knew of any drug which would benefit my patients, whether used by the homeopathist, or the eclectic, or the so-called "herb doctor," I should use it; in operating on the prostate gland, if it seems best to me to operate by the suprapubic route, I shall do so. If I elect the perineal it will be because I think that I can give the patient better prospects for an ultimate cure with less risk to life. I do not believe that it is necessary to make a minute and painstaking dissection of the perineum, nor attempt in the vast majority of cases to preserve the ejaculatory ducts.

Most of our cases are in men well past sixty, and at the time that they come to us these patients are impotent, not only as regards their powers of procreation, but as regards their power of sexual relation, and the conservation of these powers is a matter of absolute indifference.

The median perineal incision, with opening of the membranous urethra, dilatation of the vesical neck and enucleation of the prostate masses through the lateral walls of the urethra can be done rapidly and thoroughly and will give one as perfect results as any other method of operation. There is rarely any hemorrhage, if we keep with the capsule, using the finger as a blunt dissector.

There are certain cases in which the relation between the capsule and the gland and the surrounding tissues is so intimate that enucleation as such cannot be accomplished. It is said that these cases can be better removed by *morcellement* than through a suprapubic opening.

This means rather a wide destruction of the vesical mucosa.

For my part, I think that these masses can be removed through the perineal incision, modified to give a broader exposure of the field, and it is in these cases that I believe in the technique of Young, using a tractor within the bladder, as causing less destruction of the bladder tissue than can be accomplished in any other way. It seems to me that the question of injury to the rectum has been very much magnified. If we use the exaggerated Trendelenburg position, with the thighs strongly flexed on the abdomen, we shall find that the rectum falls aways very readily from the prostate. The only question of anatomy that I shall raise in any operation through the perineum will be to keep close to the bulb dividing the recto-urethralis muscle and keeping outside the fascia of Denonvillier.

One thing which has run through the entire list of topics, if you notice, very much like a *motif* in music, although not named, has been the question

of diagnosis. Beyond what has already been said of this, I am disposed to say a little something as regards the use of the cystoscope, and also touch upon the differential diagnosis.

There is one condition in which the cystoscope is of very great value; that is, where we have an enlarged middle lobe, with comparatively small amount of hypertrophy to be felt by rectal touch.

If we can get the instrument into the bladder at all, it gives us a very good view of the extent of this enlargement and enables us to choose our method of attack with reference to the ease of reaching the trouble. On the other hand, to use the cystoscope needs a large amount of special training, or the observations are not only not of value, but they are absolutely dangerous. These cystoscopes which depend upon air inflation of the bladder, and in which the opening or the prism is situated at the end of the tube, the so-called direct cystoscope, are of no use in this condition. We need a simple instrument with a prism on the concave side and water dilatation of the bladder. To use the instrument with any satisfaction, we must follow the procedure of Young, of Johns Hopkins, who has devised a scheme for reconstructing the inverted cystoscopic image and patching together the detached picture segments to give us a schematic representation of the whole field.

In the average case of prostatic hypertrophy the cystoscope is of no practical value. There is, however, one condition of the bladder as determined by the cystoscope which justifies us in diagnosing prostatic hypertrophy without being able to feel same. I refer to the trabeculated bladder, which almost invariably is significant of enlarged prostate, with more or less urinary retention.

It is particularly important to differentiate hypertrophy of the prostate gland from new growths of the same, especially malignant disease; although in cancer we are told that hematuria is one of the symptoms, yet it occurs perhaps in not over 25% of the cases.

In the early stages the most prominent symptom for differentiation is pain. The pain of cancer is much more severe than the pain of advanced hypertrophy, if such occurs; is sharper, more lancinating and very apt to radiate in the groin and down the leg. In fact this radiation, if we omit the coincidence of stone, is almost pathognomonic of cancer of prostate. A little later we get the stony hardness so significant of malignant disease. My records give me a total of eleven cases of malignant disease of the prostate, only one of which, so far as they have been followed, has shown hematuria. All but two have had severe pain; in fact that was the first symptom noticed by the patient, and for which he sought relief. The increase in size of the prostate had not been very marked prior to the onset of cachectic symptoms.

Manifestly it is important to exclude malignant disease before we decide upon operative measures, for with the one exception where the cancer is contained entirely within the capsule of the gland, operation is absolutely hopeless.

Then, too, simple hypertrophy of the prostate gland, or a congestive condition which has passed beyond the actual acute stage, calling as they do for two entirely different lines of treatment, should be carefully distinguished.

Retention of urine, difficulties in urination, in fact, practically all the symptoms that go with hypertrophy, are present in this congestive state. Even residual urine can be found, without the evidence, however, of any cystitis. This condition may persist for many weeks. Its treatment, however, is merely the employment of massage, instillations to the membranous and prostatic urethra; perhaps also enemata of hot water or the irrigation through a metal closed tube of hot water by way of the rectum.

Then, too, we should differentiate between a primary pyelo-nephritis, to which the cystitis is secondary in a man well past fifty, who in the natural order of events would possess a prostate gland which to the touch is more or less enlarged. Exclusive of the actual retention of urine, he may possess all the symptoms of the sufferer from prostatic hypertrophy, and only the most careful consideration of the previous history will help to establish the diagnosis; and it is in this type of case where operation for the prostatic trouble is practically almost always contra-indicated.

We cannot use a cystoscope to catheterize the urethra, on account of the dangers of increasing the infection and causing uremia; nor is it going to be of very great value should we succeed in securing the urine from one or both kidneys, for the reason that the whole question hinges on the fact of the infection being of an ascending or descending character. As regards the existence of stone in the bladder, the operation for relief of the hypertrophy of the gland will serve for the removal of the stone. In other words, there is a limit to the size of the stone which may be removed by way of the perineum. There is practically no limit to the size of the stone which may be removed by the suprapubic operation.

Abscess of the prostate gland may simulate acute prostatitis and, with the exception of tuberculosis and what is practically a chronic abscess, comes into conflict with the prostatic hypertrophy but very rarely. Save as in massive acute abscesses, I think that the ordinary prostatic abscess should be evacuated through a perineal incision and not by the old method of a curved trocar thrust into the abscess through the rectal wall or by incision through the rectal wall. Incision through the rectum is, however, I think justified in those large abscesses which pronouncedly bulge into the rectum, and often by pressure bring the rectal walls practically together.

Cysts of the gland require no especial mention. If large enough to give symptoms, they require evacuation and, of course, are better done through perineal incision. It is largely a matter of indifference whether we diagnose cyst of the prostate or hypertrophy of the prostate.

If we find a cyst we stop with our evacuation.

If we find hypertrophy we simply proceed and enucleate the gland.

Tuberculosis of the prostate is rarely a primary disease, usually being secondary to tuberculosis of the testicle and seminal vesicles, and in those rare instances where we find it as a primary focus, its symptomatology will be largely that of abscess, either acute or chronic, and its treatment will be surgical only in so far as it is an abscess.

During the year, in the course of my office practice, I see a great many cases of chronic gonorrhea with all its complications, and I find that daily I am either examining or treating by massage several cases in which there is apparent enlargement of the prostate gland.

These cases, of course, are simple cases of prostatitis, and yet they are undoubtedly on the road which will bring them in later life to hypertrophy of the prostate. Coincident with these cases, and really the cause which keeps alive the prostatitis and the gonorrhea, is inflammation of the seminal vesicles, and it is really by the emptying of these vesicles, through massage, that we improve and cure the gonorrhea and, to a large extent, the prostatitis, although in long-standing cases it is my opinion that changes have taken place in the prostate from which the gland never recovers.

An analysis then of what I have said to you to-day resolves itself practically into the following: A plea for the education of the public as we meet members of it in our offices, in regard to the dangers of neglected prostatic hypertrophy. A plea for the earlier recognition by the physician and surgeon, and after a careful hearing of all the evidence, the advice to the patient of a much earlier operative interference than has heretofore been the custom, for the sake of cure of symptoms and conditions and the danger to life itself. A plea not to send the patient to a surgeon who elects, or to perform yourself, a suprapubic or a perineal operation without due regard for all the facts in the case, but to advise your patient, and so do yourself, that which shall be the best for the individual concerned, remembering that time in operative work is a very great feature, in the fact that it lessens anesthetic shock in a patient already on the downward path of life.

Of course it goes without comment that this saving of time shall not be at the expense of clean, smooth work, nor is it necessary on the other hand to exaggerate infinitesimal details.

There is no place in the surgery of to-day for either the putterer and bungler, or the man who is all "front" and gallery play, when dealing as we are with life, attempting to the best of knowledge and ability to keep it from fluttering into the "Great Beyond."

Johns Hopkins Needs New Buildings.—President Remsen of Johns Hopkins University urges the immediate need of increased accommodation for the work in pathology in the medical school. From the beginning, this department has occupied a building owned by the hospital which has become inadequate in size and equipment.—*Jour. Amer. Med. Asso.*

THE TREATMENT OF SIMPLE INFECTIONS OF THE STAPHYLOCOCCUS AUREUS WITH THE "VACCINES OF WRIGHT."

BY H. F. HARTWELL, M.D.,
AND
ROGER I. LEE, M.D.
(*From the Pathological Laboratory of the Massachusetts General Hospital. J. H. Wright, M.D., Director.*)

In many cases vaccine treatment is complicated and requires the application of special knowledge, but we have found that there is a certain type of infection in which the vaccine treatment is conspicuously successful and at the same time straightforward and simple. This type of infection consists of localized surface infections, such as boils, carbuncles and septic wounds. In practically all of these cases it is fair to assume that the offending organism is the staphylococcus aureus. Our communication is based on an experience with about one hundred of such cases, which have been obtained mainly from the wards and Out-Patient Department of the Massachusetts General Hospital.

We have found that it is not necessary to prepare the vaccine from the identical organism of the lesion, an "autogenous vaccine," but that these cases do equally well when treated with a vaccine of staphylococcus aureus derived from any source, a "stock vaccine." The stock vaccine is prepared according to Wright's method and put up in bottles of 50 cc., each cubic centimeter of which contains 600,000,000 dead organisms. We have found that vaccines are not so efficacious after they have been kept for two months, and we therefore prepare fresh vaccines about every six weeks. They are preferably kept in a cool, dark place.

In many of our earlier cases we followed the opsonic index, but we have found that equally good results could be obtained without the index. We have inoculated our patients at intervals of four days. This period had been arrived at by the early studies on the index by the writers and by Dr. Roger Kinnicutt, and by watching the clinical manifestations of the lesions. We give as an initial dose ½ cc. containing 300,000,000 organisms and at the second inoculation a full cc. or 600,000,000. This last dose is repeated every four or five days until the lesions are cleared up. As a rule two or three inoculations will clear up a single focus; a boil will have discharged and dried up while a carbuncle will have sloughed out and left a clean and granulating base. Most cases will have regained their natural immunity and will require no further treatment. Some, however, will not regain their immunity for a longer period, and during that time inoculations to provide an artificial immunity are necessary to prevent a recurrence of boils. These patients have been inoculated at intervals of seven days for three or four times after their acute lesions have been cleared up and then they have been instructed to report for inoculation immediately on the appearance of the smallest pustule. By these infrequent inoculations we have found it possible to prevent the recurrence of lesions during

a period of six months in a patient who has not been free from boils for two years.

The inoculations are given deep into the subcutaneous tissues (previously sterilized with alcohol), preferably in the abdomen or back, choosing a region which is free from the pressure of clothing. A fresh site is taken for each successive inoculation to avoid the production of a local immunity. We have always boiled our syringes and have had no suppuration or anything more serious than a trifling discomfort at the site of inoculation. A slight constitutional reaction is sometimes noted, especially after the first inoculation. It has been present in about one half of our cases and usually shows itself in headache, backache and lassitude. These symptoms appear a few hours after inoculation and have entirely disappeared in twelve hours. We have never seen changes in temperature, cutaneous eruptions, or arthralgias, such as frequently follow the inoculation of sera.

The changes which take place about the lesions are striking. There is a marked diminution in the pain and tenderness. After twenty-four hours there is a profuse discharge which continues until the focus clears up. If the lesion has already broken down and is discharging no further opening need be made, but if the pus is still confined a small opening should be given for drainage. Opening up wide areas of tissue and curetting delays the reparative process. According to the experience of Wright antiseptics nullify the action of the opsonins and have not been used. The pus has been absorbed into sterile gauze. When sloughing tissue has been present it has been removed with forceps. We have occasionally seen lesions disappear during treatment without breaking down.

We have selected a few cases from those which we have treated which will serve to illustrate different types. We are well aware that simple boils tend to cure themselves, but we can only say that patients so afflicted prefer treatment by vaccine to any other method to which they have been subjected. The following is a case of simple boil:

CASE T., about one week before had a boil on neck, which was opened twice and wicked. Neck was sore all the week. Now for two days has had red, indurated tender boil on neck, with some constitutional symptoms. He was given 300,000,000 of stock vaccine of staphylococcus aureus. In the morning the constitutional symptoms had disappeared, the boil was discharging freely and there was no tenderness. In four days only the scab remained. At that time a second inoculation of 600,000,000 was given.

With boils about the face this treatment is of value as it prevents unsightly scars as in the following:

CASE P., a middle-aged woman, was seen with a boil the size of a dime, just to the left of the upper lip. The skin at its summit was broken down and there was a slight discharge. She received two inoculations. Four days after the first the boil had discharged freely, all tenderness was gone, and a slight induration, with a serous ooze at its summit was all that remained. A cocoon dressing was kept on during treatment to absorb the discharge.

The great advantage in treating carbuncles with vaccine is that they can be healed in a shorter time without a radical operation and the patients can be at work while under treatment.

CASE H., a young man, first seen on June 11, with a carbuncle on the back of his neck, which was of ten days' duration. It was two inches in greater diameter. He received three inoculations. The sloughing tissue was removed with forceps, as it loosened, and on June 19, all that remained of the lesion was an area of clean granulations the size of a dime, with a surrounding zone of indurated tissue. There had been severe pain until the night after the first inoculation, when the patient had a comfortable night. The pain did not return.

Cases of chronic furunculosis can be cleared up and kept free from serious recurrences.

CASE G. The patient was a doctor, who for several years had had boils of various severity. These had been incised, excised, cauterized, treated by crude carbolic, etc. He presented several typical boils on his neck and one on his face. These were all tender, some discharging. No local treatment was attempted. He was given 300,000,000 of the stock staphylococcus aureus vaccine. He was inoculated at irregular intervals of four to ten days. He stated that the inoculation took the pain out of the boils almost immediately, but that they recurred after six days. He was then inoculated every four days for four times. After the third inoculation the lesions were all cleared up. He has had no serious lesions since then, three months ago. He is emphatic in stating that the present treatment was the easiest and most effectual he had ever had.

Most abscesses with good drainage will promptly heal, but there is a certain definite type which will remain sluggish and indolent and will not clear up, as the following case shows:

CASE A. N., a young girl with axillary abscess which was incised and drained. In spite of good drainage considerable induration persisted, which did not yield to hot poultices. There were numerous small pustules about the wound. After ten days she was referred to one of us and immediately given 300,000,000 of stock staphylococcus aureus vaccine. Four days later the induration was largely gone and the wound was healing fast. She was subsequently given four more inoculations of 600,000,000 at four-day intervals, the last inoculation being given after the wound had healed.

We have observed a very few cases which have not responded well to treatment. Cultures from these cases have shown them to be infections with staphylococcus albus or streptococcus. Administration of appropriate vaccines has been followed by a prompt response. These cases are rare.

CONCLUSIONS.

1. Treatment with vaccines is the most effectual treatment for boils and carbuncles.

2. Although the vaccine treatment does not prevent recurrence, cases of chronic furunculosis can be absolutely controlled by occasional inoculations.

3. Vaccine treatment is a valuable surgical adjunct in appropriate cases.

4. The treatment of this class of cases can be successfully carried out without the estimation of the opsonic index and without any special technical training.

A CASE OF RABIES.

BY CHARLES F. WITHINGTON, M.D.,
Visiting Physician, Boston City Hospital.

H. M., aged fifteen. Errand boy in a grocery store. Father and mother living and well. No history of insanity or extreme nervousness in either side of the family. Patient is the third of eight children, six of whom are now living, and none of whom have ever had any nervous symptoms. While pregnant with this child the mother had no illness or injury, and the delivery was normal.

The patient had scarlet fever at four years. He has always been a wilful child. Seven years ago he received a blow above and to the outside of the right eye, which has left a depression in the skull. Since this blow he has been subject to headaches and vomiting, especially if he became very tired, and more often during the hottest days of summer. The attacks last only one day.

Six months ago he was treated at the Massachusetts General Hospital for "lung trouble."

Patient entered my service at the Boston City Hospital March 31, 1907.

On Dec. 17, 1906, when near his home in East Boston, he was bitten on the left side of the upper lip by a dog which at the time was sick and which died about twenty minutes after biting him. The dog's body was disposed of by some boys and the subsequent attempts of the Board of Health to find the body were unsuccessful.

The bite produced a lacerated wound of the lip, which was immediately dressed at the Relief Station, and the following day he was admitted to the City Hospital, on the surgical side.

He remained in the hospital one week and the wounds were dressed with iodoform wicks. Some pus discharged from the wounds and the sutures were removed at once. The night after he was bitten he was nervous and slept poorly. He had no chills and no headache.

After being discharged from the hospital he appeared to be well and continued so till March 29 (one hundred and two days after being bitten by the dog).

On that day the boy was kicked by his father, and was deeply grieved at the assault, having always been on very friendly terms with his father. He had headache that afternoon; no vomiting. Felt very nervous. The next day the nervousness increased and the mother noticed that he could not swallow; also that he acted queerly. These symptoms grew rapidly worse until he entered the hospital.

At entrance he had a flushed face; temperature 98.4°; pulse 88; respiration 20. Pupils equal and react to light and distance; expression of the eyes somewhat staring. A small depression in outer table of skull was observed to the right and above the right orbit.

Heart of normal size; action regular and of good strength. Faint systolic murmur heard over precordia, best at apex. Chest and abdomen otherwise negative. Knee jerks present, equal.

The boy was very nervous, somewhat irritable. He tossed about with almost incessant motion of some part of the body. He was mentally clear and talked incessantly about himself and of how many things he had had the matter with him. Said he had been written up in the papers and appeared rather proud of it. He complained of dryness and tightness in his throat. Something seemed to be gripping him there. His arms and body thrashed about. About every thirty seconds he jumped up in bed and expectorated very forcibly, as if he had something unpleasant in his mouth which he wished to expel as quickly and thoroughly as possible. What he spat was a frothy, rather thick saliva. There appeared no excess of saliva in the intervals of the spitting. The spitting in each case followed a gasp for breath.

His condition appeared rather hysterical, but he did not cry. On being ordered to keep still, he made an evident effort to comply, which was successful for a few seconds, after which he would again spring up and spit violently. At entrance he swallowed milk readily. He drank water also, but with more apparent effort, draining the glass, and with slight twitching movements afterward. The next morning he took a boiled egg, but only a little milk. He swallowed water when told to do so, but immediately afterwards had clonic convulsions lasting a few moments. There was, however, no hydrophobia. The sight of water did not disturb him and he even asked for it.

On April 1 the picture was as already described. He referred to the fact that his condition had been spoken of in the papers and that people had talked much about him; that he had had "many kinds of sicknesses." The movements of his body were sudden and violent. Once his hands were observed in the position of tetany, but pressure over the upper arm failed to reproduce the spasm. Generally the motions were those of a jactitation. Preceding the spitting and apparently the cause of the sudden up-spring was a sound in the throat as of a laryngeal or pharyngeal spasm which subsided after the expectoration. He spat with great violence.

No Babinski, Kernig or Oppenheim reflexes. Patellar reflexes normal. Sensation good.

Patient still exerts an obvious mental control of his jactitation for a few seconds when warned to do so.

The following history from the time of the last note till the patient's death, some seven hours later, is from the notes of the house officer:

On the same day, April 1, patient was given his clothes about 1 P.M. with the idea that he might be more comfortable in a chair, as he was so restless in bed. A few minutes later he fell out of chair and had clonic movements of hands and legs, with extreme salivation. He was then put back to bed.

During the afternoon the symptoms grew worse. Restlessness increased and salivation became marked. About 2 P.M. the patient became wildly delirious, with extreme clonic movements of arms and legs, laryngeal and pharyngeal spasm and marked cyanosis. Large amounts of reddish froth exuded from nose and mouth. Patient had extreme dyspnea, rolling of eyeballs and an intermittent sharp, high-pitched cry. He moved head from side to side, with jaws opening and shutting spasmodically, but made no noticeable attempt to injure any one. Transfer of patient to lower ward was accomplished at this time, with considerable struggling and resistance on his part. Morphia gr. $\frac{1}{4}$ was given at this time. As soon as patient reached the ward ether was administered and convulsions controlled. Color improved after etherization and spasm of larynx ceased to some degree. On recovering from ether (3 o'clock) he was somewhat quieter, though markedly excited. He seemed to know that he was in a hospital, and for a few moments at a time would be practically clear mentally. At other times he had delusions of persecution. He kept repeating that while everybody seemed to think that he had hydrophobia, he was sure he did not have it, and that if his hands were untied he would act quietly and behave himself. He also kept asking for water, and stated he was sure he could drink it without trouble. The pulse at this time was 160, of fair volume and tension. Heart sounds clear and sharp, soft systolic murmur at apex, no enlargement to right. Condition remained about the same for one hour (4 P.M.) when patient was offered water.

As soon as he saw the glass his convulsions came on again with increased force, extreme cyanosis of face with spasm of larynx and pharynx; large amount of froth coming from nose and mouth. He was again etherized, and following etherization remained quiet for about fifteen minutes, when he had another convulsion. Ether was again administered, with ¼ gr. of morphia. Pulse slightly more rapid, but volume and tension remained about the same. From this time convulsions became more severe, and he remained in this state until 6.05 P.M. Pulse remained fair in quality up to this time, when it suddenly disappeared at wrist. Heart sounds became rapid and feeble; area of dullness increased to right mid-clavicular line. Convulsions ceased, cyanosis became extreme and patient died quietly at 6.10 P.M.

The autopsy, as will be seen, demonstrated besides the Negri bodies which are believed characteristic of rabies, a persistent thymus, general lymphoid hyperplasia and a small aorta, which mark the so-called status lymphaticus, often the cause of sudden death in children.

The essential features of the autopsy have been kindly summarized by Dr. F. B. Mallory as follows:

"The post-mortem findings in this case may be briefly summarized as follows: Three irregular scars on the face; moderate general edema of the subcutaneous tissues; marked dilatation of the right side of the heart; congestion and edema of the lungs; persistence of the thymus gland, which weighs 23 gm.; hyperplasia of the lymphoid tissue throughout the body; slight internal hemorrhagic pachymeningitis; small cyst of the pituitary body; mypoplastic aorta.

"Microscopic examination shows fatty degeneration of moderate degree in the heart and kidney, and marked in the liver and intima of the aorta.

"The histological examination of this case is not yet finished, but so far as completed shows nothing remarkable except the presence of the Negri bodies, which are characteristic of rabies, in the Purkinje cells of the cerebellum. They occur in the cytoplasm of most of these cells and frequently also in the cell processes. In numbers they vary from one to seven or eight. The size is quite variable, but many large, oval forms of characteristic appearance occur. The bodies show the well-known acidophilic staining reaction and stand out very distinctly in sections stained by the anilin blue connective tissue method.

"The cerebrum and cord have not yet been examined."

SOME PERSONAL EXPERIENCES IN ABDOMINAL SURGERY.*

BY A. C. HEFFENGER, M.D., PORTSMOUTH, N. H.

THOSE surgeons whose professional life embraces from thirty to thirty-five years have enjoyed the privilege of seeing the most wonderful advance in the field of surgery the world has ever known. Although advancement has been general, and brilliant achievements have been wrought in every branch, it is in the abdomen that the greatest strides have been made, and the boldest work done. During my entire course as an undergraduate, I never saw the abdomen opened intentionally by a surgeon unless it was post-mortem. Even suprapubic cystotomy was shunned, and stone removed almost invariably by perineal section. In the early seventies of the last century I assisted in the first ovariotomy I had ever seen, and the crudity of the technique and disastrous results of the operation are indelibly impressed upon my memory. The patient was a woman, about fifty years old, who had a large multilocular cyst of the right ovary. The operator and his two assistants simply washed their hands in the usual everyday manner, and wiped them on towels taken from the washstand. The operator wore a white apron, and the assistants were simply in shirt sleeves. The woman's abdomen was washed with ordinary soap and water, and a steam atomizer on an adjacent table threw carbolic spray over the abdoman and upon the operator and his assistants. A number of surgical needles of various sizes and no particular form were threaded with silk and stuck into the waistcoats of the assistants, and silk cut for ligatures was hooked over the needles so as to be handy to pull off and tie. Of course neither needles nor silk had been sterilized. A large, waxed silk ligature, consisting of half a dozen strands of silk twisted together, intended for tying off the pedicle, lay on a table with the instruments. The instruments were simply washed, dipped into a carbolic solution, and then placed on a table covered by a nonsterile towel. An incision from umbilicus to pubis was made, and a rough hand was forced around the tumor in all directions to break down the numerous and dense parietal adhesions. Pieces of peritoneum several inches in length were stripped off, and afterward found hanging to the cyst walls. An attempt was then made to deliver the cyst with the hands, but, of course, failed, and the operator plunged a trocar into the various cystic sacs, and squeezed out the contents over and into the abdomen. When the cyst was finally delivered, the pedicle was tied off in two sections with the waxed ligature before mentioned, the cyst cut away, and the ends of the ligatures left about one inch long. Small bleeding vessels were tied with the silk ligatures taken from our waistcoats, and the abdominal wound closed by through-and-through silk sutures from the same waistcoats. There was a bit of rubber tissue, which had been previously immersed in the carbolic solution, placed over the wound, the abdomen was wound several times with a bandage swathe, and the case was finished in more senses than one. Septic peritonitis ensued, with death on the fifth day.

This was the beginning of Listerism in America, and the spray and carbolic solution were relied upon to prevent infection. What a hopeless delusion! What a contrast to the scrupulous, scientific technique of to-day, and what a difference in results. Shortly after this I saw an ovariotomy done by an English surgeon in South America, who claimed to have been a pupil of Lister. The technique was fully as crude as in the one previously mentioned, but fortunately the woman lived, owing, I believe, to the fact that the pedicle was sutured in the abdominal wound, and buried; unsterilized ligatures were left in the abdomen to infect it. On my return to the United States a few years later, Listerism *per se*, had

* Read at the annual meeting of the New Hampshire State Med. Soc., May 17, 1907.

passed, and the beginning of modern aseptic surgery had set in. Drainage, however, in nearly all abdominal operations was a rule, showing a sad lack of faith in the principles of the new doctrine preached. The tube gradually gave way to temporary gauze drains, with an early closure of the wound, and bolder men closed more and more wounds without drainage, until finally confidence became general, and all non-septic or slightly septic abdomens were closed at once. The advent of the salt solution was a great aid in forwarding abdominal technique, and enabled many doubtful abdomens to be closed, thus diminishing the mortality rate and post-operative suffering, and hastening recovery. It is still good surgery in many sections with immediate closure of wound to leave a quart or more of salt solution in the abdomen, for it certainly prevents sepsis, and through its rapid absorption increases the blood volume, diminishes shock and alleviates thirst. The interval operation in appendicitis was a distinct advance in the surgery of the abdomen. For many years surgeons had been opening abdominal abscesses which presented against one of the walls, but were not emboldened to open a nonsuppurating cavity till asepsis came to their aid, and made it clear that invasion of the peritoneum under proper precautions was a perfectly safe procedure. When this fact became generally known the offending, and often unoffending, appendix was attacked with a vigor that fairly took the breath away from the older surgeons, and made the civilized world stand aghast with fear and wonder. The introduction of the Lembert and other intestinal sutures, together with Halsted's demonstration of the holding quality of the fibrous layer of the intestines, and the invention of the Murphy button and other anastomotic contrivances made practically a new field in the surgery of the abdominal alimentary canal. Intestinal anastomosis can be still further improved by the use of a sterile, absorbable scaffolding, say in the form of oval or round bobbins of various sizes made of gelatin and starch or dextrine, so that they would liquefy in the intestinal juices in from twenty-four to forty-eight hours. I have had patterns of these made from which moulds could be cast, and have asked several surgical dressings manufacturers to put their chemists to work to make a suitable absorbable material. To effective hemostasis with sterile and absorbable suture material, however, probably more than to any other advance, we owe our great achievements in abdominal and intrapelvic surgery, for this alone has changed the mortality rate in the graver operations from 50% to 5%. A quicker appreciation of anatomical appearances, enabling more rapid and accurate work, is another distinctive advance. Improved handicraft has lessened the size of the wound, and this, with a better knowledge of closing and treating it, has diminished mortality and suffering, with fewer subsequent herniæ.

Twenty-five years ago, abdominal surgeons were few, and were practically to be found only in metropolitan centers. Now, however, every small city is blessed with one or more, and it is no longer necessary for patients to travel hundreds of miles to obtain able and skillful operators. Many emergency cases, requiring immediate operation, and which were generally fatal, are now happily saved, thanks to the local surgeon.

No branch of surgery requires such quick comprehension of an ever doubtful problem, more ready wit, or resourcefulness. However sure one may feel of a diagnosis, it is better to qualify it till after the operation, for great surprises that may sorely tax one's ingenuity may be encountered. To illustrate I will briefly relate some cases from my own practice.

Case I. A young married woman, aged twenty-eight, mother of one living child, with no previous history of pelvic or abdominal trouble, and in apparently good general health, was sent to me with what was supposed to be a cyst of the right ovary or broad ligament. A tumor extended from the right flank to the right lobe of the liver, and thence across the abdomen under and above the umbilicus, for several inches, to the outer border of the left rectus muscle. A guarded diagnosis was given. A median incision extending above and below the umbilicus was made, and the boundaries and attachments of the tumor carefully explored. It was found to be a cyst of the pancreas, arising by a broad base from the head of the organ, and extending over the region previously mentioned. The cyst was evacuated, a part sutured to the abdominal wound, the cavity packed with gauze, and drained with a tube. She made a good recovery.

Case II. A man, aged thirty-seven, entered the hospital with violent symptoms of intestinal obstruction which had existed for several days. He gave a history of left inguinal hernia, and had worn a truss. Examination showed the left inguinal canal to be wide open, with nothing foreign in it. The finger could be passed readily into the abdomen. There was great tympanitis, and vigorous movements of the small intestine could be seen through the abdominal walls. By deep pressure a mass could be felt in the left hypogastrium. Several consultants pronounced it volvulus. As the hernia had not been down for some time, and no sac was found in the canal, incarceration seemed doubtful. The abdomen was opened by median incision, and the mass found to be a hernial sac the size of a grape fruit, with a pedicle attached to the internal ring. In the opposite free end of the sac was an opening the size of a ten-cent piece, through which a part of the small intestine entered and emerged. The opening was enlarged and about two feet of apparently viable intestine pulled out. The empty sac was obliterated by two purse-string ligatures, and the abdominal wound closed. Recovery uneventful.

Case III. A schoolboy, aged sixteen, developed symptoms of intestinal obstruction May 15, 1898. Two days later violent peritonitis set in, with infantile vomiting, fecal in character. His condition became grave, and his physician sent for surgical assistance. He was found in collapse. Inspection of abdomen showed an irregular prominence of the abdominal walls about two inches in size, and two inches to right of umbilicus. The tumor was very sensitive to manipulation, and doughy to touch. Inquiry elicited a history of congenital umbilical hernia, with fecal fistula. The hernia disappeared, and fistula closed a few months after birth. An umbilical truss was worn for some time as a safeguard. The patient was stimulated vigorously, and under ether an incision several inches long was made opposite umbilicus, and along outer border of right rectus muscle. A spur of ileum was found

crossing the middle of the wound to under surface of umbilicus, where it was closely adherent, as well as to adjacent peritoneum under right rectus muscle. Firmly attached to this spur at the umbilical end was the appendix, and wound round both appendix and spur were several coils of small intestine, dark, lusterless and barely visible. General peritonitis existed throughout the abdomen. The appendix was removed, the spur of gut dissected free, the intestinal coils unwound, and the abdominal cavity flushed with hot salt solution. The patient rallied some after the operation, but relapsed next day, and died from continued peritonitis.

CASE IV. A grass widow, aged twenty-seven, was admitted to the hospital with a history of sudden and sharp pain in lower abdomen, followed by great prostration. This had occurred several days before medical aid was summoned. When seen by a physician she was in bed and very weak, sallow and blanched, but no pain. She was ordered to hospital for exploratory laparotomy, which was done on the tenth day after her sudden illness. She most emphatically denied pregnancy, and was highly indignant at the bare suggestion of such a thing. The abdomen was enlarged and slightly tympanitic, and there was nearly 2° of temperature. A median incision was made, and a large quantity of dark fluid blood escaped through the wound. A hand was passed into the abdominal cavity, and while removing large clots, encountered a fetus lying loose and detached. It was removed and found to be about three months old. The abdomen was then thoroughly flushed with salt solution, wiped dry, and the wound retracted to give a good view of the pelvic contents. There was a mass occupying the left side of the pelvis, from which blood slowly oozed. This was firmly attached by a broad base, and every effort to detach it was followed by copious hemorrhage. The mass consisted of placenta and thickened and altered tube and broad ligament. A clamp was applied at the pelvis brim and another one at the uterus, and the entire region packed off with gauze, the ends of which came out at the lower angle of wound, the upper half of which was closed with through-and-through silkworm-gut sutures. Transfusion finished the technique. The patient rallied well, and clamps were removed the following morning. The gauze packing was removed on the fifth day, and an attempt was made to remove some of the placenta. Several fair sized pieces were picked off, when hemorrhage became so severe that clamps had to be applied and the region repacked with gauze. This process was employed from time to time, and as the placenta necrosed it came away easier and without much hemorrhage, so that in six weeks it was all removed, when the wound filled in rapidly and closed.

CASE V. A young married woman, aged thirty-three, married several years, and was never aware of being pregnant, menstruation erratic and excessive since girlhood, flowed two-thirds of the time during past six months, several months ago realized that there was a tumor in lower part of abdomen. During the week previous to admission to hospital had suffered from nausea, vomiting, pelvic pain, fever and sweating. Examination showed a large, nodular uterine fibroid, and hysterectomy was advised and agreed to. A median incision from umbilicus to pubis was made, and with much difficulty the tumorous uterus was delivered upon the abdomen. As the broad ligaments were a mass of large, venous sinuses and newly formed arteries, the difficulty of controlling hemorrhage made the operation a slow one. After the uterus was isolated down to its neck, amputation was begun, and when the cervical canal was opened, a small brown foot prolapsed into the pelvis, and amniotic fluid escaped. The canal was hastily plugged with gauze, and the amputation completed. The subsequent steps of the operation were completed as hurriedly as possible, and as oozing persisted and the patient's condition was bad, a couple of clamps were left on and the wound closed down to them, a provisional suture being left untied. Transfusion was done, and the patient gotten into bed. Next morning the clamps were removed and the suture tied. Shock was severe for several days, after which she convalesced rapidly. The uterine mass was laid open, and a small cavity was found in the right side of it containing a three months' fetus, dark brown, and partly decomposed.

CASE VI. A woman, thirty-nine years old, married, rather tall and stout, weighing 180 lb., in previous good health, was suddenly seized with violent pains in hepatic and epigastric regions, radiating under right shoulder blade. She was visiting at a farmhouse on the coast of Maine about fifteen miles distant. A local physician was called who administered morphia without relief. A physician from Portsmouth was then called in consultation and decided she was suffering from biliary colic, and in grave shock. I was telephoned for in the evening, about twelve hours after onset, to come prepared to operate. On arriving at 11 P.M., she was found collapsed from agony of pain, and operation was at once decided upon as offering the best chance of recovery. As rapidly as possible the sitting room of the farmhouse was made into an operating room, the kitchen table being pressed into use for an operating table. Three kerosene lamps were obtained, affording meager light, and a sand bag had to be dispensed with as not obtainable in reasonable time. With the local physician to give ether, and the Portsmouth consultant to assist me, a cholecystotomy for exploration of biliary passages was begun. The obesity of abdomen, together with absence of sand bag, made it necessary to use the Mayo-Robson extended incision, and even with this it was most difficult to deliver the gall bladder, though it was free from adhesions. Poor light made it practically impossible to see beyond the fundus of the gall bladder, so this was seized with tenaculum forceps and pulled up, while the index finger of right hand palpated the ducts. This detected an obstruction in the cystic duct near the neck of the gall bladder. The fundus of gall bladder was then incised, and a finger passed inside to neck, while the index finger of the other hand milked the obstruction back. Soon three small stones passed back into the gall bladder, and were removed. A searcher was then passed through cystic and common ducts freely, finding nothing. Further palpation from head of pancreas to hilum of liver revealed nothing, so it was decided that the cause of trouble had been removed. The fundus of gall bladder was stitched to parietal peritoneun, a drainage tube inserted and secured by suture, the wound sutured above and below the drainage, a gauze wick passed down to the fundus, dressings applied, and patient put to bed in a fairly good condition. There were no complications; the tube came away in a week, and the wound closed completely in about five weeks. This case illustrates what may be done in emergency under most disadvantageous circumstances.

CASE VII. A single man, aged thirty-seven, wiry build, high liver and free drinker, was seen in consultation the third day after having had violent colic with vomiting. Two weeks previously be had experienced a like attack after eating eggs and drinking a lemon squash. This attack followed similar eating and drinking, and naturally was considered the same in character, and in view of subsequent developments, the two

attacks up to a certain stage may have been alike. Saline purgatives and high enemata were recommended and close observation of the case enjoined. I may say that at this time the abdomen was flat, there was no specially tender point, and no abnormality on palpation. Temperature normal. Two days later I was called in consultation again and found conditions much worse. Well marked intestinal obstruction existed with intestinal bunching across hypogastrium. General condition fair in spite of gravity of case. He was sent at once to hospital where median section was done and rapid exploration of abdominal cavity made. General twisting of the ascending colon and ileum was found to exist, and the intestines above stricture being enormously distended, nothing could be done till an incision above the umbilicus was made and the entire mass delivered on the abdomen under hot towels. Then it was found that the ascending colon was devoid of mesentery for the first two thirds of its length, and at the ileo-cecal junction the small and large intestine had turned over and over till about half a dozen twists existed. The difficulty of unwinding this tangle was great, and after it was accomplished and the intestinal canal was free it was found that the enormous gaseous distention made it impossible to return the viscera to the cavity without evacuation of gas, and puncture of the cecum was done. This collapsed the gut, after which the wound in cecum was closed, intestine returned and abdomen closed as rapidly as possible. The patient's condition was most grave, requiring transfusion and all possible stimulation. He rallied at first and inquired particulars of his case, but collapsed from shock afterward and died in six hours.

Case VIII. A young man, twenty-six years old, presented himself for examination, declaring he had appendicitis, and thought an immediate operation was necessary. Examination revealed a linear scar along the outer border of the right rectus muscle opposite McBurney's point. Inquiry elicited the fact that he had been operated upon previously and his appendix removed. He insisted, however, that there was constant pain in the appendical region which was unbearable. There was rigidity of the abdominal muscles, and apparent pain on pressure. No tumor evident, and percussion sounds normal. It was considered probable that sensitive adhesions existed, which might be freed by operation, and the abdomen was opened parallel with the old scar. There was no appendix, the first operation having evidently disposed of it, but the cecum was bound down by dense adhesions, as was also the ileum for a short distance beyond the ileo-cecal valve. These adhesions were freed as far as possible, and the abdominal wound closed. Convalescence was rapid, and the man was out in a couple of weeks. He went to a city in an adjoining state, and in a couple of months apparently had another attack of local pain, for he called in a prominent surgeon and told him he had appendicitis and desired to be operated upon at once. What the surgeon thought upon seeing two scars upon the man's belly I never heard, but he proceeded to investigate the inside of it, and, of course, found only some adhesions. The man was soon out again, and presumably happy and contented at having had his abdomen opened three times for appendicitis. This state of contentment did not last long, for a few months afterward he turned up in a hospital in another New England city, and informed the house surgeon he had appendicitis and wanted to be operated upon without delay. The visiting surgeon after examining the abdomen and viewing the scars of many surgical combats, made a careful investigation into the history of the man, and upon finding him an operation crank declined to operate, and had him discharged from the hospital. This man undoubtedly had a monomania for abdominal section, or what might be called the operation habit, and had he not been firmly dealt with by the fourth surgeon to whom he applied, might have been still wandering from hospital to hospital, seeking inspection of his viscera, or else have died from operative interference. The rebuff he met with finally cured him, and induced him to enter the field of medicine in a legitimate manner, as he is now a general practitioner.

THE QUESTION OF "JUSTIFIABLE HOMICIDE."

BY CHARLES GREENE CUMSTON, M.D., BOSTON.

(Continued from No. 15, p. 497.)

And, lastly, one should also exclude from among crimes from passion those which are merely cases of rape disguised. All these crimes cannot be considered as crimes from passion, because they are not disinterested crimes, neither are they directly caused by passion. Their motive is not love, but in reality is *amour propre*, the regret of lost habits and cupidity. It is also to be pointed out that when jurists ask for a severe sentence in all cases of crimes from passion, it is usually to these crimes from pseudo-passion that they refer.

It unfortunately happens to many men to be amorous, jealous and deceived, and when they discover it they become indignant and are pained, but the larger number silently suffer, forget or become resigned to it. Only a few revolt against the moral law by avenging themselves by crime. Nevertheless, all of them undergo the same sentiments. The indignation for the traitor, anger for the unfaithful seducer, the resentment of outraged honor in the husband and maternal love are sentiments, not only normal, but moral as well. Everyone has them under such circumstances and we all should have them. For a proof we have only to recall the esteem in which a woman indifferent to her children is held, or a husband who cares little for his honor.

Even jealousy is, without any doubt, a natural and general sentiment in man, although it is a low order of sentiment, since it is derived from egotism. The reasons why these sentiments develop in an excessive manner in certain people and become abnormal on account of their intensity are as follows, and we will examine these individuals from the standpoint of their character as well as their mental condition. The sentiment which, in the first place, seizes passionate individuals is the absence of will, and these subjects are weak. The absence of control over oneself is what characterizes these unfortunates, and is both the result and the cause of their physical and moral stigmata. For this reason it is astonishing that a psychologist as eminent as Stendhal should have considered them as energetics. The only application is in the sense that Stendhal gives to the word energy which, according to him, is the violence, the sudden blind explosion, having no design and no outcome, of a passion which cannot be either repressed or controlled. These energetics are merely impulsive subjects who are lacking in force to resist themselves. As Stuart

Mill remarked, it is less on account of the ardor of their desires that men fall into evil than from the weakness of their will. There exists a natural relationship between a passionate character and a feeble will, in this sense, that passion does not develop in those who know how to overcome it by self effort as soon as it arises. These subjects never obey other than their own will, and consequently cannot be considered passionates. On the other hand passionates are not only weak, but they are presumptuous and consequently imprudent; instead of taking the fruit, instead of putting aside a passion which will be fatal to them, the danger of which is all the greater the weaker they are, they believe that they are stronger and more skillful than others, and from this time on, they, in reality, have everything to fear. Afterwards, when suffering has taken the place of the happiness of their passion, they excite it, instead of appeasing their chagrin. It is a fire which consumes them and makes little difference to them if they die from it, but, unfortunately, they do not wish to die alone. Instead of assuming a perfect outward tranquillity, so that this calm may become real after having stimulated, they become pleased in their chagrin and love their suffering.

The best proof of this will be found in the descriptions that they all make, even the greatest, like Goethe, or Musset, of their story and their misfortunes. The worst cases are those which will not allow themselves to be cured, because the only thing in life that they care for is the sensation of their suffering. Later, when they find themselves in face of the crime and wish to retract, it is too late. As one of them said, "At one time I was perfectly free. My heart was unfettered, and nothing was easier than to separate myself from my thoughts; every one gave me this advice and I thought that I would always be sufficient master of myself, but imprudence wrecked me." It is just at this time that the responsibility should be looked for in this class of criminal although it is quite particular and social, rather than moral. Their mind is still free, the heart unfettered, but the subject, being persuaded that he is stronger and more tactful than others, throws himself in the same river in which others have been lost. With this confidence in himself it is not at all astonishing to meet with an extreme susceptibility and an immense *amour propre*.

Laffarge, the ebonist worker and the hero dear to Stendhal, when questioned regarding the motives of his crime, replied, "I wanted to avenge myself upon her, as her disdain rendered me crazy." Another subject gave better evidence as to the motive of his crime when he said, "I was too proud to submit to this affront, and honor demanded me to take revenge."

This question of honor plays a great rôle in crimes, but if a husband can feel wounded in his honor from reason of the one who bears his name, he must nevertheless have an exceptionally high opinion of himself in order to believe that he has the right to destroy a human existence from this fact. And what is still worse, it has been shown that the husband does not always have such a delicate sentiment for the honor of his hearthstone, and that the mere fear of being ridiculed occasionally makes him an assassin. This susceptibility may, as has been pointed out, go as far as ideas of persecution. To sum up this side of the character that we have just been examining we would say that the passionate is extremely personal. Jealousy, in the first place, is a proof of love, without any doubt, but ordinarily it shows more *amour propre* than love. It must be said that everything is not sacrifice of devotion in lovers, and an unconscious egotism frequently occupies a large place in their sentiments. What is not easily borne when breaking off is the happiness of the one that they leave. The lover becomes consoled when he knows that his former mistress is unhappy and, if she returns to him, he may perhaps pardon her, but if he learns that she is happy and that she loves another, his jealousy will no longer pardon her, his love changes to hatred and he wishes to take revenge.

If we now study this same criminal from passion in the physiological point of view, we will find the explanation of his character and also some little excuse for his acts. According to the great Italian criminologist, Ferry, he is physically a man possessed of a sanguine or nervous temperament, contrary to born criminals who are lymphatic subjects. This first remark abounds in proof, and Proal says in his most interesting book that "it has been observed that jealous subjects who become assassins have a red face, congestion of the brain and the eyes projecting. It is said that he sees red, because he is blinded by the blood." A witness said, speaking of a husband who had killed his wife, that "the face was violet, and one would have said that he had a congestion of the brain." In another case a witness testified that the assassin was very red in the face and in a condition that he had never seen him before, while another witness added that the assassin was so red in the face he could no longer see, because the blood blinded him.

The accused that we have mentioned were evidently of a sanguine temperament, while, on the contrary, subjects like Chambige, Soularue and Marie Bière were evidently of the nervous type, and, among the papers belonging to the first mentioned, this cry of despair is found: "*Oh ma mere, pourquoi m'avoir donne des nerfs de femme!*" Born into the world nervous and sick, these individuals could be saved by a severe moral discipline, but ordinarily everything that surrounds them simply tends to exasperate their nervous type. As Maudsley has remarked, those who have this temperament have a sort of elective affinity for subjects having the same mental qualities and the same moral tendencies, and they afterwards share the defects of character. This simply tends to develop their nervous nature, and modern life, especially in cities, is not at all calculated to calm very excitable natures.

Without speaking of that part of the population in which the uncertitude of the morrow strains

the nervous system by the uneasiness it causes, in the easy classes, the abuse of pleasures and excitement, prolonged dissipation, have rendered nervous diseases frequent. On the other hand, the ordinary necessities of life are the cause of many neuroses. The struggle for life which is all the time becoming more difficult, professional rivalry, preoccupation of business produced by an always increasing competition, produces intellectual and physical overwork which fatigues the nervous system.

For the working class one may add to these causes the vibrations of machinery, insufficient nourishment, or meals too hastily eaten, and lastly, and above all, alcoholism.

The proofs of this general neurosis are to be met with even in our pleasures, the taste for violent emotion, dangerous sports and everything that overexcites the nerves. The intelligence of neurotic subjects is in no way affected, but their will power suffers. Energy becomes an extremely rare virtue, and we more frequently meet brilliant minds than firm characters.

We have said that the criminal from passion is essentially a feeble being and, according to our way of thinking, the reason is this: If, as it has been upheld, crimes from passion have increased in number, the cause is to be looked for in the increase of nervous diseases. The physiological state of criminals often presents stigmata more serious than a disease of the nervous system, and one is struck by the large number of these criminals who show mental disease in their family antecedents. Many of them have had insane, vicious or alcoholic parents, who have a certain part of responsibility in their children's crimes. One should not assume that these indviduals are irresponsible, but merely that they are less well prepared to fight against their passions.

The question is particularly delicate, because we constantly find ourselves face to face with subjects who certainly are not sufficiently insane to be placed in an asylum and who, on the other hand, it would be difficult to call absolutely and fully responsible. To acquit them and send them back to liberty is perhaps imprudent, but, on the other hand, it is neither right nor useful to society to condemn them. It is quite possible that all criminals do not belong to families tainted with insanity, although this is met in a very large number of cases, but for all, at least, passion is a dissolvent of the will. Gall has said that all men have the germ of a monomania in the existence of a passion. This is because passion is essentially absolute and nothing exists beyond its goal. It begins by requesting, afterwards it commands and finally compels its victim to act. Although there may have been a struggle there may be a final defeat of the health. Usually, it is true, there is no struggle because the idea opposed to the passion does not even come up. The mind has been corrupted before the will, and before imposing an act the passion has obliged the idea to be admitted as just.

Among all the passions love certainly would appear to have a decided aspect of a monomania, and one of the most eminent in the study of mental disease, I refer to Dr. Paul Janet, gives it this character. He points out that everything in this passion resembles insanity in its origin, its development and mechanism. In the first place it does not depend upon the will, because "*il ne suffit pas de vouloir être amoureux*," any more than to wish to cease to be.

On the other hand, there is a period of incubation, as in all virulent disease; the idea accomplishes its underground work and only reveals itself in its full activity, like a fire which smoulders only to suddenly burst out in all its violence.

(To be continued.)

Medical Progress.

REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D.,
AND
HARVEY P. TOWLE, M.D.

HISTOLOGY OF THE CHANGES CAUSED BY THE RÖNTGEN RAYS IN MALIGNANT TUMORS.[1]

No one at present can deny the very favorable influence of Röntgen rays on malignant neoplasms, and especially on certain forms of cutaneous cancer. Writers are not, however, in accord as to the exact way in which the Röntgen rays act in this astonishing and quite elective manner. Some consider that the first action of the Röntgen rays is to produce a reactionary inflammation of the connective tissue, or believe that the blood vessels are damaged in the first instance. By far the greater part of the authors, however, believe that there is a primary damage of the cancer cells by the Röntgen rays. In other words, that there is a primary degeneration of the cancer cells while the inflammatory reaction is only secondary.

Marschalko's histological studies were based upon material from 4 cases, 3 cases of cutaneous epithelioma, and 1 case of multiple sarcoma, Kaposi's type. The epitheliomata represented three different types of cells, and the tumors were all examined before and after treatment with the Röntgen rays. The conclusions which he arrived at from his investigations are that soon after the beginning of treatment an intense reactionary inflammation is produced, with thickening of the epithelium, infiltration of the tissue with leucocytes, and much dilated and partially new formed vessels, swelling of the endothelial cells, partially with thickening of the intima and breaking up of the media, and with the formation of a considerable cell infiltration consisting, for the most part, of plasma cells. This cellular infiltration is soon accompanied by a connective tissue proliferation which in later stages leads to a considerable hypertrophy of the collagenous tissue with the formation of giant cells. This hypertrophy progresses from the periphery toward the center, and undoubtedly has a tendency to

[1] Von Marschalko: Arch. für Derm. und Syph., lxxxiv Band, 1-3 Heft.

bring about a walling off of the specific tumor elements.

Hand in hand with this inflammatory reaction there is also a change and degeneration of the tumor cells. In carcinoma the karyokinetic figures are very small in the parts reached by the Röntgen rays, the growth is checked, and the cancer cells undergo degeneration and necrosis.

The whole process, however, has its beginning at so early a period that it is impossible to conclude that the change of the cancer cells is only secondary and brought about by the reactionary inflammation. On the contrary, the writer's investigations tend to strengthen the belief that the cancer cells are primarily damaged by the Röntgen rays.

He does not, however, believe that the reactionary inflammation is simply a consequence of this primary damaging of the cancer cells, but believes that there is also a primary damaging of the connective tissue by the Röntgen rays, which leads to a great increase in the inflammatory infiltration and proliferation of the connective tissue. He was not able to determine whether the vessels were first and most seriously affected.

Primary damaging of the cancer cells and also of the connective tissue appear, therefore, to be quite independent of one another as the result of the action of the Röntgen rays.

The question arises whether this degeneration of the cancer cells is specific and only connected with the action of the Röntgen rays, or whether it is simply a quantitative increase of the processes of degeneration which are more or less constantly occurring in cancerous tissue. The writer inclines to the latter view.

In the later stages, at least, the reactionary inflammation appears to play an important part in breaking up the specific tumor elements. This is seen by those appearances in which the cancer nests are found surrounded by leucocytes; these press not only between the cancer cells, but partially within them. Hence he concludes that the leucocytes play an active rôle in the destruction of the cancer cells.

With regard to the sarcomata few conclusions can be drawn from his investigations, as it was not a real sarcoma, but a so-called sarcoid tumor.

With regard to the important and practical question how deep the Röntgen rays can penetrate in cancer, his investigations support those authors who believe that the action of the rays does not penetrate very deeply. His microscopical preparations show that only the more superficial masses of the tumor are destroyed at first, and even in such cases where there is apparently no carcinomatous tissue to be seen under the microscope carcinoma cells are still to be found singly in the deeper tissues. That these cells may take on a further growth is proved by one of his cases in which there was a recurrence after what was apparently complete healing and after an interval of half a year.

As to the question whether there is a difference in the different forms of cancer with respect to the action of the Röntgen rays, the writer's investigations point to the conclusion that such a difference does not exist, as all of the forms which he investigated reacted in the same way.

DIPHTHERITIC INFLAMMATION OF THE SKIN.[2]

There is very little to be found in the newer textbooks on dermatology on the subject of diphtheria of the skin. Primary diphtheria of the skin is a rare affection, meaning by this a diphtheritic lesion of the skin caused by the direct inoculation of diphtheria bacilli at the spot, and not of inoculations of the skin which are continuous with diphtheria of the mucous membrane.

Five cases of inoculation of the skin with demonstration of diphtheria bacilli were observed in the University clinic in Breslau during the 'ast year and a half. In three of these pure cultures were obtained, and their virulence proved by experiments on animals. Three of the cases from which the bacilli were obtained from pure culture were very much alike clinically. All were in children from one and one quarter to two and a half years of age, and the lesions were purely ulcers, in the beginning of very small dimensions and extremely superficial. Later they became confluent, and usually quite large. Their form was very irregular, as the edges formed polycyclical bows or deep sinuses into the normal skin. The edges were slightly infiltrated, very intensely reddened, and only here and there somewhat undermined, and they were usually pretty sharply cut out. The floor of the ulcer was covered with a grayish white, firmly adherent diphtheritic membrane. There was very little odor. After the ulcers were cleansed, there was a speedy formation of granulation, and recovery was quite rapid. These ulcers were situated especially about the abdomen, groins and genitals. In none of these cases was there any affection of the mucous membrane, nor were there any discoverable signs in the internal organs. Diphtheria serum was injected in all these cases, and they all did well, but it is questionable whether any inferences on this score can be drawn from so small a number of cases. No trace of a toxin could be found in the blood.

The fourth case is that of a child of three, in whom the affection took the form of an infantile ecthyma. The localization was a peculiar one, the larger ulcers being in the lower abdominal and inguinal region, whereas ecthyma usually affects the extensor sides of the extremities and back. The lesions began as small pustules with an inflammatory areola. In their further development, the roof of the bullæ was broken and superficial ulcerations were formed. The ulcers were rounded, the edges surrounded by a small red areola. The floor of the ulcers was covered with a yellowish covering. Diphtheria bacilli were found by staining and by culture in only one of the larger ulcerations. Pure cultures were not obtained, nor was there any result from animal inoculation.

In the fifth case, that of a man of thirty-one,

[2] Schucht: Arch. für Derm. und Syph., lxxxv Band, 1-3 Heft.

diphtheria bacilli were obtained from a deep ulcer covering the dorsum of the penis and a part of the mons veneris. Later, when the ulcer had become smaller, the spirocheta pallida was found.

The number of cases of diphtheria of the skin with the presence of Löffler's bacilli which have been reported in the last years is small. In most of the cases in which diphtheria bacilli were found there was an infection of deep wounds, abscesses and other subcutaneous infections. In these the typical diphtheria membrane is not formed, and these affections differ in no way from the pictures which can be produced by other pyogenic affections. The writer thinks that his first 3 cases are typical enough to warrant a probable diagnosis of diphtheria of the skin from clinical appearances alone, and the most characteristic appearances he considers to be the irregular form of the ulcers, the diphtheritic covering, and the localization.

LUPUS ERYTHEMATOSUS AND LUPUS VULGARIS.[3]

The writer thinks that there is sometimes a doubt between the clinical diagnosis of lupus erythematosus and lupus vulgaris. It is evident that we do not yet know all of the cutaneous manifestations of tuberculosis. Apart from the forms already recognized, such as lupus vulgaris, acute miliary tuberculosis of the skin, etc., there are a certain number of cases which surely belong to tuberculosis, or are related to it, which it is not possible to definitely classify. In the face, especially, there is a series of affections which may reach the subcutaneous cellular tissue, which belongs in this group. If lupus erythematosus and lupus vulgaris were related etiologically, it seems that the combination of the two processes would occur more frequently. In point of fact, this association is extremely rare. Even in the well-known case of Besnier and Lacavalerie, there was no histological examination.

On the question of the tubercular nature of lupus erythematosus, the dermatological world is divided, one side affirming this etiology, the other denying it. Arning believes in the tubercular origin, and bases his belief upon the frequent presence of tubercular adenitis. He has experimented with Koch's tuberculin and obtained some general reactions, such as headache, erythema, etc., but never fever or local reaction. Boeck found in 36 personal observations, signs of scrofula in two thirds of the cases, and believes in the possibility of a toxic origin. Besnier regards lupus erythematosus as tubercular in its nature, basing his conviction on the existence of intermediate clinical forms between the two types of lupus, their coexistence and the frequency of tubercular adenitis. The same arguments are used by Jeanselme and Hallopeau. Jarisch considers the cases which are regarded as combinations of the two types of lupus as errors of diagnosis. He does not deny that tuberculosis plays a part in the appearance of lupus erythematosus, but protests against the assimilation of the two affections. Kaposi protested against the unitarian theory, but declared that those who were affected with lupus erythematosus are often tuberculous, and said that he had never seen this affection in old people. Koch, in 37 cases, has seen two of pulmonary tuberculosis. Jadassohn and Neisser consider lupus erythematosus an infectious granuloma, and reject all association with tuberculosis.

The case is reported of a man of thirty-seven, who was admitted in 1896 in Kaposi's clinic, with a diagnosis of lupus erythematosus. Three years later he was admitted to Lang's clinic, with lesions on the right and left cheek. The plaque on the left cheek was sharply bounded, pigmented, and of a cicatricial appearance, covered in places with scales, and in the cicatrix there were nodules either confluent or isolated, which were unquestionably lupus vulgaris nodules. On the right cheek there was a similar lesion, cicatricial, with reddish-brown nodules on its lower border. The diagnosis was a combination of lupus erythematosus and lupus vulgaris. The lesions were excised, and microscopical examination of the plaque on the left side verified the diagnosis of lupus vulgaris. Seven months later, the patient returned to the hospital with a further development of lupus erythematosus, and some years later another outbreak was observed. Histologically the characteristics of both lupus erythematosus and lupus vulgaris were found. In two sections from the nodule of lupus vulgaris tubercle bacilli were found.

This is the third case only in the literature of this association of the two affections. It is quite possible, in view of the rarity of such observations that the association was simply a coincidence. The histological examination of this case proves conclusively the presence of tubercles of lupus vulgaris, some writers having questioned whether in cases previously reported masses of elastic fibers undergoing a colloid degeneration have not been taken for lupus nodules.

VON RECKLINGHAUSEN'S DISEASE.[4]

An interesting case of this affection occurred in a widow, forty-five years old, who came to the hospital, complaining of painful itching tumors of the skin. She said that they had first appeared when she was twelve years old, five or six in number. They were seated mostly on the trunk and steadily increased until they were very numerous. None ever disappeared spontaneously. They all gave rise to extreme itching and pricking pains. Several of the growths removed at the hospital when she was thirty years old had reappeared. Her general health had been good with the exception of fits at various times.

Upon examination it was found that the patient was very neurotic and of variable temper. She was quite thin, and the skin atrophic. Some of the tumors were pedunculated, loose and soft; others firm and obviously arising from the subcutaneous tissue. The pedunculated growth seemed to cause more itching, while the firmer ones were more tender and painful. There was

[3] Spitzer: Ann. de Derm. et Syph., March, 1907.

[4] Malcom Morris and Wilfred Fox: Brit. Jour. of Derm., April, 1907.

no pigment upon the body, as is usual in such cases.

While she was in the hospital for a period of months, there was a series of epileptiform fits, which were considered hysterical in character.

Six of the growths were excised and examined microscopically. The two varieties of growths differed considerably when they were cut open. The pedunculated growths apparently consisted of loose, fibrous tissue, while the sessile ones were gelatinous and firm. Staining by several methods showed in sections fine nerve fibers arranged in bundles between the layers of fibrous tissue. The small tumors were seen to be fibromata made up of spindle cells.

The points of interest in the case are the absence of any large pendulous tumors, the fact that apparently no large nerve trunks were involved, that only very fine fibers in the skin were involved, and the hysterical convulsions.

Reports of Societies.

AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION.

TENTH ANNUAL MEETING, HELD AT ATLANTIC CITY, N. J., JUNE 3 AND 4, 1907.

THE President, Dr. HENRY WALD BETTMANN, of Cincinnati, in the chair.

THE EVOLUTION OF GASTRO-ENTEROLOGY.

DR. BETTMANN, in his opening address, said the most important change in the spirit of internal medicine during the past quarter of a century had been the swinging of the center of gravity from the pathology of structure to the pathology of function. Twenty-five years ago pathological anatomy and histology were beginning to lose their force as a means of medical progress; they were becomng sterile from over-cultivation, and had ceased to reveal new truths. An entirely new point of view became absolutely essential to vitalize research, and this new point of departure was afforded by bacteriology, which in an amazingly short period became a well-organized science. At the same time, rapid advances in organic chemistry rendered possible the development of new methods of research, and chemical pathology became a fertile department. Chemistry and bacteriology had rejuvenated pathology, making it seem like a young science capable of unlimited development and growth. Every branch of internal medicine had been quickened by the change.

INCOMPLETE FORMS OF EXOPHTHALMIC GOITER IN RELATION TO GASTRO-INTESTINAL DISORDERS.

DR. J. P. SAWYER, of Cleveland, in this paper, said that gastro-intestinal processes were intimately associated with vasomotor conditions. These in turn were markedly affected by the hyperthyroidism, which at present was recognized in exophthalmic goiter. This hyperthyroidism existed in many cases which did not show the "cardinal signs." Routine examination of all cases for diagnostic recognition of disturbed vasomotor function, due to this cause, might show its existence in patients not having the symptoms of goiter of this type developed to such a degree that attention would be attracted to them in the course of an examination made without having that point in mind. It was thought to show, at least in the writer's vicinity, the greater prevalence of the disorder than was commonly noted; also, that therapeutic procedures based on special examination of stomach contents and feces might be considerably assisted by measures adopted to meet the recognized development of exophthalmic goiter. Among these measures were climate, hydrotherapy, electricity and various drugs, including the antithyroidin of Moebius, and thyroidectin. Special note was made of the effects of atmospheric conditions, particularly of relative humidity. Note was also made of certain blood findings.

DR. A. L. BENEDICT, of Buffalo, said the thyroid gland was very unstable in its functions, and especially in young girls I found all kinds of disturbances, some with goiter, some without, and in all these cases the personal equation of the examiner must not be lost sight of. The speaker referred to the comparative frequency of thyroid disturbance, not only in gastro-enterologic, but also in general, practice.

DR. J. A. LICHTY, of Pittsburg, said he had used thyroidectin in a number of cases with somewhat doubtful results. Those cases in which it apparently had most effect were young girls at about the age of beginning menstruation, with enlarged thyroids and evidences of hyperthyroidism. Many of these, doubtless, would have done equally well without the thyroidectin.

DR. J. KAUFMANN, of New York City, referred to the profuse diarrhea, which was at times the only pronounced symptom of an incomplete exophthalmic goiter, and said that instead of being due to vasomotor disturbance, as suggested by Dr. Sawyer, it was possible that it was the result of the toxins which were such a prominent factor of exophthalmic goiter, and which were perhaps excreted by the intestines. Based upon that idea, he had employed colonic irrigations in these cases with good results.

DR. I. ADLER, of New York City, said he had seen many cases of exophthalmic goiter, in which almost the only subjective symptoms were of the gastro-intestinal type. Chemical and bacteriological examinations of the urine, blood and other substances in these cases gave very variable results, and were of no practical benefit. The speaker referred to the use of rodagen in these cases. It was expensive, but those patients who were able to afford it were apparently benefited by it. It had practically the same effect as the antithyroidin of Moebius, but had the advantage of being a distinct food, and to that extent counteracted the emaciation.

DR. MAX BALLIN, of Detroit, said he treated all his cases with thyroidectin, and he could affirm what had been said regarding the efficient qualities of rodagen. He was opposed to the use of iodine in these cases, as it usually aggravated the symptoms of hyperthyroidism.

DR. SAWYER, in closing, said the ages of his patients ranged from that of children two or three years old to people advanced in years. They included both sexes. His experience with antithyroidin and thyroidectin had convinced him that the effect of these remedies was positive, but less effective when used alone than when combined with physical measures.

A NEW BLOOD TEST.

DR. MAX EINHORN, of New York City, demonstrated this method. He stated that examinations for the presence of blood have increased in significance since Boas reported the occurrence of occult blood as an almost constant symptom in carcinoma of the stomach. Usually, the aloin or guaiacum test was employed for the demonstration of the blood, and recently a new test

with benzidin had been described by O. and R. Alder. Both the guaiacum-aloin and the benzidin tests require the preparation of fresh solutions, which render them more difficult. Dr. Einhorn therefore tried to simplify the test by making a reagent paper. He prepared an aloin paper and a benzidin paper. Aloin paper was made by saturating ordinary filter paper with a solution of aloin in 70% alcohol; the benzidin paper by moistening filter paper with a saturated solution of benzidin and glacial acetic acid, and drying it. In preparing the paper, as well as in making the test, it was of importance to avoid contact with the fingers, as a drop of perspiration caused a similar reaction. In handling the paper it was best to use an ivory-tipped forceps, or protect the hand by means of a towel. Aloin paper was much inferior in sensitiveness to benzidin paper. He, therefore, recommended the latter.

CASES OF TRUE INTESTINAL DYSPEPSIA.

Dr. Max Einhorn, of New York, read this paper. He stated that by the expression "intestinal dyspepsia" we understood conditions in which the digestive function of the intestinal tract was disturbed. It was advisable to distinguish two large groups of intestinal disturbances: 1. Those which concerned all these classes of food substances, namely, albuminates, carbohydrates and fats; dyspepsia intestinalis universalis. 2. Those affecting only certain classes of food stuffs; dyspepsia intestinalis partialis. This second group might be further subdivided, according to the varieties of foods, the digestion of which was disturbed. These functional disturbances of the intestinal digestion might exist without appreciable anatomic change of the digestive apparatus, or they might be associated with lesions of that tract. The idea of testing the functions of the intestine in a similar manner as those of the stomach prevailed among clinicians for a long time, but its execution was attended with great difficulties. By means of the bead test, which Dr. Einhorn demonstrated at a meeting of the association a year ago, an approximate estimate of the work of the intestine became possible. The method was easy to apply and the results were sharply defined. By a large number of examinations, the results of which would soon be published, he had become convinced that the digestive functions of the bowels might be well judged by means of this test, and he saw no reason why it should not be utilized in the study of diseases of the bowel. In using the bead test, if we found a substance in the beads undigested, it should not be taken for granted that no digestion whatsoever of such substance might occur in the bowel. That would be wrong, for the same food stuffs in liquid form might still be well digested. We could only conclude from this test that there was a considerable diminution of the digestive power for those substances.

Dr. H. W. Bettmann, of Cincinnati, said he had used these beads in some forty instances, and the conclusions he had derived from them were very similar to those of Dr. Einhorn. In a certain number of cases where he had employed them, only the potato substance was passed unchanged, indicating a carbohydrate intestinal indigestion. Because of the simplicity of the bead test, suggested by Dr. Einhorn, it would probably eventually have a wide application.

The discussion was continued by Drs. A. L. Benedict, of Buffalo, and J. C. Johnson, of Atlanta, and was closed by Dr. Einhorn.

(To be continued.)

Book Reviews.

The Prophylaxis and Treatment of Internal Diseases. By F. Forchheimer, M.D., Professor of Theory and Practice of Medicine and Clinical Medicine, Medical College of Ohio; Department of Medicine of the University of Cincinnati, etc. New York and London: D. Appleton & Co. 1906.

This book of Dr. Forchheimer fills a distinct need in American medical literature. Its scope has been limited wisely to two phases of the art and science of medicine, prophylaxis and treatment, with only a few necessary excursions into the other phases of medicine. It is a field not occupied fully by any other recent book. A book of such scope is a useful addition to the library of every practicing physician because it contains information for daily use in an accessible form. Frequent personal reference to the book during the past six months has proven it to be of much value, and on these grounds it is recommended rather than on the basis of a hurried review.

Most of the therapeutic suggestions receive the approval or disapproval of the author because in his own experience they have shown themselves useful or not. In fact, comparatively little of the work is based on other than first hand knowledge, though due credit is always given to the originator of every procedure. Methods not sufficiently tried by the author are given, however, with the opinion of some good authority as to their value. It is not to be expected that the reader will concur in all that is said, and a number of the reader's pet modes of treatment may be undescribed or subjected to adverse criticism. However, treatment based on the directions of this book will be rationally conservative and form a most excellent foundation from which, with experience and cautious experiment, the practitioner can gradually develop an efficacious therapy satisfactory to himself.

The general arrangement of the subject matter is excellent. In places, however, there is a distinct lack of smoothness of diction which detracts from an otherwise satisfactory book. Fortunately this is more evident in the preface than elsewhere — though to find it in the first few pages brings it with undue force to the attention of the critic. In a number of places through the book, there is an uncertainty of meaning which does not disappear on close analysis of the sentences. This results from a somewhat loose use of pronouns which might refer to one of several things, and the occasional heading of a paragraph in a way suggestive of a division of the subject into several parts, whereas in fact no such sub-division is carried out.

Rather more mistakes in spelling and use of words occur than should. The very frequent use of the active form, as "is doing," "is making," in place of the passive form "is being done," "is being made," jars on the ear. These, however, are minor defects to be righted in subsequent editions, and do not seriously detract from the

value and usefulness of a book which presents so many good features. The list of drugs given at the back of the book does not contain a number referred to in the text. This is inconvenient as it necessitates reference to some other book. Some bibliography in the opinion of the reviewer would be an addition to a book in which various authors are so frequently quoted.

However, we understand that the demand for the book has been such as already to require a new edition, in which these minor changes can be made. No change in the make-up of the book will be needed so far as the publishers are concerned.

Cancer of the Rectum, Its Surgical Treatment, with an Appendix of 380 cases; Jacksonian Prize Essay. Fifth edition. By HARRISON CRIPPS, F.R.C.S., Senior Surgeon to St. Bartholomew's Hospital, etc. London: J. & A. Churchill. 1907.

This is a fifth edition, published thirty-one years after the first writing of that Jacksonian Prize Essay.

Readers familiar with surgical writing of the present generation know this work of Mr. Cripps', which has become almost a classic within the author's lifetime. The book, as now presented, contains 255 pages with 13 beautiful plates, and tables of cases filling 66 pages. It seems needless at this time of day to review again this well-known book. Mr. Cripps has rewritten the entire manuscript, introducing the best thought on recent investigations of the pathology, differential diagnosis and treatment of rectal cancer. We commend the book cordially to surgeons and to thoughtful students.

The Care of the Baby. By J. P. CROZER GRIFFITH, M.D., Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania. Fourth revised edition. 12mo of 455 pages, illustrated. Philadelphia and London: W. B. Saunders Comapany. 1907.

This little book, which is now, as it has been in the past, one of the best of its class, has been thoroughly revised and brought up to date. An appendix, dealing with the principles of infant feeding both in health and disease, and giving a number of formulæ, has been added for the use of those parents for who some reason are thrown upon their own resources in this matter. We agree with the author, however, that these directions and formulæ should never be made use of except under these conditions, and that otherwise the feeding, both in health and disease, should be directed by a competent physician.

Gallstones and Diseases of the Bile-Ducts. By J. Bland-Sutton, F.R.C.S., Eng., Surgeon and Lecturer on Surgery to the Middlesex Hospital, etc. With 47 illustrations. New York: William Wood and Co. 1907.

Any book from the pen of this distinguished author deserves consideration, and though the little 200-page monograph before us is unpretentious we commend it cordially to students or practitioners who look for a brief, interesting and readable presentation of cholelithiasis, to intelligent practitioners, perhaps, rather than to students, for students concern themselves little with interesting books.

Bland-Sutton gives us eighteen short chapters, and deals in a pleasantly familiar way with the anatomy, physiology, pathology and surgical treatment of the bile passages. He gives the average reader all he can care to know, while one finds in the book various descriptions and dissertations on some of the more unusual aspects of bile passage disease.

The book is unpretentious, is well printed, is illustrated in a somewhat antique fashion and is comfortably small.

Woman. A Treatise on the Normal and Pathological Emotions of Feminine Love. By BERNARD S. TALMEY, M.D., Gynecologist to the Metropolitan Hospital and Dispensary, New York. For Physicians and Students of Medicine. 228 pages, flexible covers, with 22 drawings in the text. New York: The Stanley Press Corporation. 1906.

The author of this book explains in the preface that the medical student is not instructed as to the normal sexual emotions by his professors or by his textbooks, and sets himself the difficult task of filling in this gap in the medical curriculum. It has not occurred to him, apparently, that the subject should be approached reverently by one endowed with a wide training, not only in gynecology, but in ethics as well. Love is regarded as synonymous with passion, an affair of the flesh solely; therefore, the book, although containing a certain amount of valuable information, and planned with the best intentions, is distinctly nasty. There is a lot of pomposity in the use of Latin terms, a great many headlines, and noted authors are paraded freely. The following extract from the end of Chapter 38 gives a pretty good idea of the character of the work: "While in libido the entire body is in a state of sexual excitement. This general excitement depends upon the irritation of the fibers of the sympathetic nerves. The irritation spreads over the entire extent of the vasomotoric system. Hence, with every sexual excitement ensues an irritation of the vasomotoric system. The result is a great turgor of the genitals and an increased turgescence of all organs accessible to an objective examination. The general turgescence is seen in the injection of the conjunctiva, the prominence of the bulbi of the eyes, enlargement of the pupilla to almost twice its normal size and palpitation of the heart, which is caused by the paralyzation of the vasomotoric nerves coming from the sympatheticus of the neck. The coronary arteries become thus widened, and the muscles of the heart hyperemic, hence an increased excitation of the ganglia of the heart ensues."

THE BOSTON

Medical and Surgical Journal.

THURSDAY, OCTOBER 17, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 Boylston Street, Boston, Mass.

INTERNATIONAL CONGRESS ON TUBERCULOSIS.

A preliminary announcement of the International Congress on Tuberculosis, to be held in Washington from Sept. 31 to Oct. 12, has been published. The cosmopolitan character of this congress is forthwith manifest from the fact that the text is printed in four languages: German, French, Spanish and English. This meeting will no doubt be the most important that America has yet seen in regard to the tuberculosis problem. The Federal Government has shown a decided interest in the aims of the congress, and seven of the government departments have petitioned the United States Congress for the authority and means to participate in its deliberations, these departments being the Departments of State, of the Treasury, of War, of the Navy, of the Interior, of Agriculture and of Commerce and Labor. The whole question of tuberculosis has so far outgrown the attention merely of the medical profession, and has become a national problem of such wide significance that this action on the part of the Government is in no way surprising. In addition to the Federal Government, the governors of individual states have been notified of the congress, and most of them have taken official action in consequence. In fact, all the agencies in the United States which directly or indirectly come in contact with the tuberculosis problem have been invited to offer their contributions to the general fund of knowledge which the congress will provide.

The congress will be divided into seven sections: first, pathology and bacteriology, under the presidency of Dr. William H. Welch, of Baltimore; second, clinical study and therapy of tuberculosis, sanatoria, hospitals and dispensaries, under the presidency of Dr. Vincent Y. Bowditch, of Boston; third, surgery and orthopedics, under the presidency of Dr. William J. Mayo, of Rochester, Minn.; fourth, tuberculosis in children, etiology, prevention and treatment, under the presidency of Dr. Abraham Jacobi, of New York; fifth, hygienic, social, industrial and economic aspects of tuberculosis, under the presidency of Mr. Edward T. Devine, of New York; sixth, state and municipal control of tuberculosis, under the presidency of Surgeon-General Walter Wyman, of Washington; and, finally, tuberculosis in animals and its relations to man, under the presidency of Dr. Leonard Pearson, of Philadelphia.

During the three weeks of the sessions a tuberculosis exhibition will be open and lectures by distinguished investigators will be held, together with various clinics and demonstrations. The success of tuberculosis exhibitions is already assured as a means of education, and this one, in connection with the International Congress, will no doubt be more elaborate in detail than any hitherto held. Literature will be widely distributed, and matters illustrative of the disease will be gathered from all parts of the civilized world. In order still further to insure the success of the exhibition, the committee has decided to award testimonials to meritorious exhibits. For example, three cash prizes of one thousand dollars each will be given and several other awards of smaller value.

It is intended to publish papers announced in the official program previous to their presentation before the congress. These papers, printed in four languages, will be distributed on the day they are read. It is estimated that the final publication of the work of the congress will amount to four volumes, each of about two thousand pages.

It is hoped and expected that this congress will bring together men interested in the universal scourge of tuberculosis from every part of the world, and it is certainly not to be questioned that their deliberations will be of value as summing up our present knowledge of means of prophylaxis and treatment. In this connection it is interesting to look back twenty years and legitimate to congratulate ourselves upon the enormous progress made in combating an affection which we now know could only be successfully accomplished by combined effort.

BOSTON DIRECTORY OF CHARITABLE ORGANIZATIONS.

THIS volume, bearing the full title, "Boston Directory of Charitable and Beneficent Organizations," published by the Associated Charities of Boston, is of so great value to the medical profession that we are glad to call attention to it in these columns. The first edition of this directory was published in 1880, and contained but 182 pages of text as contrasted with the 500 of this last, fifth edition. This great enlargement of the volume is evidence, not only of the general growth of the city, but also of the special development of its various agencies of a charitable character.

We speak of the directory particularly because of our desire to call the attention of the medical profession to the information it contains bearing directly on their work. Many physicians are so completely occupied with the details of their professional work that they find small opportunity to investigate the various charitable organizations with which this or any other great city is filled. If this knowledge were more widespread, there is no doubt that many puzzling problems which present themselves to active practitioners regarding the proper disposition of cases would be easily solved. The procedure necessary, for example, in dealing with the insane, or others demanding the care of the city, will be found detailed in this admirable volume, succinctly and in convenient form for reference.

Further than this a section is given over to legal suggestions in which the rights of individuals and the duties of the city in relation to the poor, illegitimate children, boarding of infants, paupers and similar matters are clearly stated. These are evidently matters about which every physician practising in a large community should know, and which, if known, he would undoubtedly find a great help in that part of his practice which deals with the unfortunate poor. A further matter of importance is a summary of the more important laws applying to dwellings in the city. In this department the organization of the health department is discussed and its duties defined. The significance of the term "nuisance," which often bears very closely on matters of health, is laid down in definite form. Garbage, drainage, infectious diseases, overcrowding, building permits, air spaces, — all these and many other analogous matters are gathered together in small compass and so arranged as to be exceedingly easy of reference. The main portion of the volume is taken up with a well arranged list and description of all reputable charitable institutions in the city, although the Directory does not assume any special knowledge of the character of these institutions, beyond the fact that they are being legitimately conducted.

We have no hesitation in cordially recommending this book to the medical profession as a valuable directory and also as a means of explicit information on a great variety of subjects with which every physician must be brought more or less into contact. As the physician enters more and more into the social life of the community in which he lives, and takes a larger share in its problems, it is evident that the need of such a directory as this of the Associated Charities will be increasingly manifest.

REPORT OF THE SURGEON-GENERAL OF THE ARMY.

THE report of the Surgeon-General of the Army to the Secretary of War for the fiscal year ending June 30, 1907, is a pamphlet of 183 pages containing many interesting facts regarding the medical conditions of the United States Army, together with the usual statistics and figures illustrative of the rise and fall of various diseases. As we have repeatedly had occasion to say, the careful tabulation of statistics regarding disease in the army, if carried out each year by the same system, must throw much light finally on the fundamental problems of the sanitation of large bodies of men. For example, it appears that malarial diseases have steadily increased in the army since 1904, a fact which has led to an investigation of the cause. Although it is now recognized that effective screening against mosquitoes is an important preventive measure, nothing has been accomplished in this regard in the Philippine Islands. Certain hospitals are absolutely without screens, and when this became known, a recommendation was forthwith made that adequate screening be provided to exclude mosquitoes. This example of apparent flagrant neglect of an ordinary precautionary measure was clearly brought to light by the unexplained increase of malarial fever. The same naturally applies to other conditions. In general, we commend this report to the careful inspection of all health officers and those engaged particularly in sanitary problems. The amount of information compressed into small compass is so great, and much of it is so significant for problems of sanitation and prophylaxis, that it will well repay careful study. Naturally, the extension of our domain into tropical countries increases the scope of this report to a very great degree.

A NEW CLINICAL JOURNAL.

We have received within a few days the first number of a new medical journal, entitled *The Quarterly Journal of Medicine*, printed at the Clarendon Press, Oxford, and also obtainable in London, New York and Toronto. The following names appear on the editorial board: William Osler, J. Rose Bradford, A. E. Garrod, R. Hutchison, H. D. Roleston and W. Hale White, with the collaboration of twenty-five other distinguished practitioners. So far as one may judge from this first volume, the journal is to be devoted to medicine rather than to surgery, a need which is apparent in the English-speaking countries. There are thirteen contributions to this number by such men as Byrom Bramwell, Robert Hutchison, William Osler and G. A. Gibson. The articles for the most part are much more than mere clinical reports of cases, and represent painstaking laboratory research. It is particularly to be hoped that the future numbers of the journal may continue to insist upon the intimate relationship existing between the clinic and the laboratory, and that the journal may therefore stand as a completely adequate representative of medicine from the broadest standpoint. There is small doubt that this policy will be followed, judging from the men who are responsible for the publication. In form the journal is dignified and entirely satisfactory. It is liberally illustrated, two plates being in colors and many others printed on special paper. Altogether, both in form and substance, the journal starts on its career with every prospect of success, at least on the literary side. It is announced that a number will be issued once in three months after the manner of the chief English neurological publication, *Brain*. We wish the journal all success.

MEDICAL NOTES.

Cholera in Russia. — It is reported that cholera is spreading in Russia.

Death of Dr. Eduard Hitzig. — In the death of Dr. Eduard Hitzig, Emeritus Professor of Psychiatry in the University of Halle, the world loses an indefatigable worker on the subtle problems of brain physiology. Professor Hitzig has long been a prominent figure in German medicine. He reached the age of seventy years.

Endowment for a Hospital. — By the will of the late Miss Anna T. Jeanes about $5,000,000 is said to have been left for public purposes, among others the establishing of a hospital. A large bequest was made to Swarthmore College conditional upon the abandonment of intercollegiate sports. The decision of the board of managers has not yet been made public.

Entering Medical Classes. — It is stated that the entering medical class at McGill University is smaller than usual, attributable probably to an increase in the requirements and to the fire which destroyed one of the most important buildings. The entering class at the Harvard Medical School is this year somewhat larger than for several years previously. A considerable number of those coming to this school for the first time this year have applied for advanced standing.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Oct. 16, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 43, scarlatina 40, typhoid fever 23, measles 4, tuberculosis 30, smallpox 0.

The death-rate of the reported deaths for the week ending Oct. 16, 1907, was 19.51.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Oct. 12, 1907, was 212, against 178 the corresponding week of last year, showing an increase of 34 deaths and making the death-rate for the week 18.14. Of this number 112 were males and 100 were females; 207 were white and 5 colored; 138 were born in the United States, 66 in foreign countries and 8 unknown; 44 were of American parentage, 135 of foreign parentage and 33 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 35 cases and 3 deaths; scarlatina, 38 cases and 0 deaths; typhoid fever, 27 cases and 1 death; measles, 6 cases and 0 deaths; tuberculosis, 35 cases and 13 deaths; smallpox, 0 case and 0 deaths. The deaths from pneumonia were 16, whooping cough 1, heart disease 30, bronchitis 1 and marasmus 14. There were 11 deaths from violent causes. The number of children who died under one year was 65; the number under five years, 79. The number of persons who died over sixty years of age was 45. The deaths in public institutions were 79.

There were 4 cases and 1 death reported from cerebrospinal meningitis during the week.

Nurses in the Boston Schools. — Although the new system of school nurses has been in use but a short time, results are apparent. As the principal of one school expressed it, "The nurses

are supplying the medium between the school and the home." It is said that the chief difficulty which the nurses encounter in the prosecution of their work is the ignorance of parents. This is not surprising in view of the limited intelligence of many with whom the schools and the nurses come immediately into contact.

Children's Clinic at Consumptives' Out-Patient Department. — Within a few days the first clinic for children at the Boston consumptives's out-patient department has been held. Twenty presented themselves, but none were found with positive symptoms of the disease. One object of this out-patient department is to discover the disease at the very earliest time, and in general to do missionary work regarding fresh air and good food, even if signs of the disease have not actually appeared. A gratifying amount of work has already been accomplished by this addition to the city's means of combating tuberculosis.

Ether Day at the Massachusetts General Hospital. — As has been the custom for some years past, Oct. 16 was celebrated at the Massachusetts General Hospital as "Ether Day," being the sixty-first anniversary of the surgical use of ether as an anesthetic. Nurses were invited to visit the hospital on this occasion; in the afternoon lantern slides were shown in the lower amphitheater of the Out-Patient building, and tea was served in the old operating room in the dome of the Bulfinch Building. The recently completed orthopedic ward was also thrown open for inspection.

NEW YORK.

College of Physicians and Surgeons. — At a meeting of the trustees of Columbia University held Oct. 7, Marcellus Hartley Dodge was elected a member of the Board of Trustees to fill the vacancy caused by the death of Dr. George E. Wheelock, and Dr. Robert F. Weir and Charles McBurney, professors of clinical surgery, were made Emeritus Professors of Surgery. The following gifts to the medical department were announced: from Bernard M. Baruch, $5,000 for the Vanderbilt Clinic, and from Mrs. George E. Wheelock, $5,000 as a fund in memory of her late husband, the income to be applied to the service of the Department of Physiology.

School of Catholic Women's Association. — The School of the Catholic Women's Association of Brooklyn has just entered upon its twelfth season. It was inaugurated by the rector of St. Augustine's Church, in the interest of the young women of his parish, whose education had been neglected, and it has gradually extended its work throughout the diocese. The association is now a branch of the State University, and among the subjects taught is nursing. The course in nursing is for young women over twenty years of age, who cannot spare the time to take a regular hospital course for trained nurses. It comprises lectures five days in the week by competent physicians, and practical lessons by a masseuse and dietitian, with instruction in cooking for invalids. At the end of twelve weeks candidates are thoroughly examined, and if they pass satisfactorily are given a certificate, which entitles them to enter upon work immediately as Nazarene nurses. After six months' practice these nurses are given a diploma and qualified to take cases for which a trained nurse is not specifically required. It is now four years since this system was instituted, and, on account of their comparatively low fees and their efficiency, the demand for these Nazarene nurses has become so great that it can scarcely be met by the graduates. They do not pose as trained hospital nurses, but in many cases are recommended by physicians in their stead.

Reduction in Death-Rate. — The weekly reports of the Health Department show a gratifying reduction of the death-rate, both as regards August and the month of September last year. The mortalityin the city during September represented an annual death-rate of 16.62, as against 20.12 in the month of August and 17.88 in September, 1906. Among the diseases in which there was a diminished fatality were the following: The weekly average of deaths from measles decreased from 13.5 in August to 4.75 in September; the weekly average from whooping-cough, from 15.75 to 6.25; from diphtheria and croup, from 23.25 to 21.5; from pulmonary tuberculosis, from 148.25 to 142.75; from broncho-pneumonia, from 87 to 59.75; from diarrheal diseases, from 440.75 to 252; from diarrheals under five years of age, from 414.5 to 233.5; from cancer, from 64.75 to 57.75; and from Bright's disease and acute nephritis, from 104.25 to 87.75. Among the few diseases in which there was an augmented mortality were the following: The weekly average of deaths from typhoid fever increased from 16.25 to 19; from lobar pneumonia, from 51.25 to 56; from apoplexy, congestion and softening of the brain, from 41.5 to 45.75; from organic heart diseases, from 114 to 121; and from cirrhosis of the liver, from 17.5 to 20.5.

3. The x-ray probably has no direct effect on the tubercle bacillus, either inhibitive or bactericidal. The action is that of stimulation of the surrounding tissues. In lupus vulgaris Pancoast finds the x-ray a specific. In this disease the x-ray has supplanted surgery, which is to be regarded only as an adjunct. In other tubercular conditions, the x-ray is to be used only in connection with other treatment. The writer reports good results with x-ray in tuberculous adenitis, laryngitis, peritonitis, cystitis and orchitis. He thinks it may be of some value in phthisis. He has seen no good results in the treatment of bone and joint tuberculosis with the x-ray.

7. McClure isolated in animals a loop of bowel, closing the ends, and at the same time restored the continuity of the bowel by an anastomosis of the free ends. The animals all died within a few days with symptoms similar to intestinal obstruction. This suggests that the symptoms of obstruction are due to intoxication from the confined intestinal contents. The writer produced chronic obstruction by reversing a portion of bowel. The animals showed no severe symptoms, but became progressively emaciated. Autopsy after several months showed a distention of the intestine greater than in most cases of acute obstruction.

10. Hatcher finds that the "cactina pillets" of the Drug Company and the cardiac tonic (cactin) of the Sultan Abbott Alkaloidal Company are inert when used on animals in doses that are even thousands of times as large as those recommended by their exploiters. [R. I. L.]

1. Crile describes his method of direct transfusion of blood by the aid of a specially devised tube, which allows him to place intima against intima, and thus avoid clotting. In the human, transfusion is made between the radial artery of the donor and a superficial vein of the recipient. The blood should be introduced very slowly, and the anastomosis continually protected from the air by constant application of warm salt solution. The blood lost by the donor is regained in from four to five days. His experience is based on 225 animal experiments, and 32 clinical cases.

3. Munro suggests that in cases of babies in whom the ductus arteriosus has failed to close, this vessel may be ligated by surgical intervention. He has demonstrated the feasibility of such ligations on the cadaver. The difficulty of diagnosis of the condition, however, makes its practical application problematical at present.

4. Stewart believes that the opening of an artery to remove either a thrombus or embolus can be readily performed without danger of secondary hemorrhage. Such a procedure is particularly indicated when the intima is smooth. It should be performed as soon as possible after the arterial obstruction develops. Even though the vessel again becomes obstructed with clot, this may form slowly, and give the collateral vessels a chance to dilate.

8. Watts gives a very careful résumé of all the literature on the suture of blood vessels, including its application to transplantation of vessels and organs. From a large amount of experimental material, he concludes that completely divided vessels can be sutured with almost uniform success, when the aseptic technique is perfect. In making the suture, he uses the method of Carrel. The vessel's ends are first united by three interrupted stitches, equally distant from each other on its circumference, and penetrating all the coats. By traction upon these guide stitches, the edges of the vessel are approximated and a continuous suture applied. The material used was silk, boiled in vaseline. All instrumental handling of the ends of the vessels is to be avoided. Out of 31 experiments upon the vessels of the neck, 28 were successful.

9. Tilton reports 20 operative cases of abscess of the lung occurring at the Bellevue Hospital. The mortality was 50%. Cases of lobar pneumonia running an irregular course, suggesting secondary empyema, should be regarded with suspicion. In such cases, he advises exploration by resection of one or more ribs; palpation and inspection of the pleura; search for an adherent area, and trial punctures of the lung through the adherent portion. Should there be no evidences of adhesion between the visceral and parietal pleura, he advises suture of these two membranes, so as to bring about such adhesions. If the suture has been done satisfactorily, the incision of the pleura can be done at once, without being put off until a second sitting. If, however, the patient's condition is good, the delay of a couple of days will doubtless insure stronger adhesions. In making a diagnosis of lung abscess, the x-ray is often of value.

11. Watson proposes the simultaneous performance of bilateral nephrostomy, tying off both ureters, and at the same time establishing permanent renal fistulæ in the loin, thus wholly diverting the entrance of all urine into the bladder. This can be done (1) as a palliative measure for cases of inoperable tumor of the bladder, as well as in cases of tuberculosis of the bladder, originating in the kidneys; (2) as a preliminary step toward total extirpation of the bladder. The apparatus which he has devised to insure permanent drainage from the renal fistula is composed of (1) a hard rubber cup-shaped shield, through which the tube that drains the cavity is passed; (2) a light metal receptacle into which the urine is conveyed; (3) a rubber tube at the bottom of the receptacle by which it is emptied; (4) elastic belts passing around the body, by which the shield and receptacle are held in place. Good illustrations of this device are given. In two instances, the writer has used it with entire success.

15. Ladd and Osgood, in examining the urine of 120 cases after etherization, found acetone present in 88.5%. These cases were all etherized with a cone, or by the semi-open method. Ether anesthesia produced by a modified drop method, using a plain pad of gauze over the the patient's mouth and nose, was followed by acetonuria in but 26%. They describe the method of etherization as follows: A square pad of gauze, twelve layers thick, and large enough to cover the patient's mouth and nose, is laid directly on his face. Ether is then dropped on this gauze by means of a drop bottle. In about a minute, a similar pad is laid on the first, and the rapidity of the drops increased. The ether should never be poured on in large quantities. The average time needed to produce complete anesthesia is about five minutes. The average amount of ether necessary is about 7 oz. per hour. It is also claimed by the writers that this method is less disagreeable to the patient, that post-operative vomiting is much less frequently seen, and that recovery of consciousness occurs more quickly than after the closed methods of administering ether. [W. C. Q.]

BULLETIN OF THE JOHNS HOPKINS HOSPITAL.
AUGUST, 1907.

1. *HAMMAN, L. *A Brief Report of the First Two Years' Work in the Phipps Dispensary for Tuberculosis of the Johns Hopkins Hospital.*
2. *HAZEN, H. H. *The Home Factor in Tuberculosis. A Study of Tuberculous Families.*
3. *HAMMAN, L., AND WOLMAN, S. *The Early Diagnosis of Pulmonary Tuberculosis.*
4. FLICK, L. F. *The Crusade against Tuberculosis.*
5. JACOBS, H. B. *The Tuberculosis Situation in Maryland.*
6. *BLOODGOOD, J. C. *Intestinal Obstruction.*
7. POHLMAN, A. G. *The Purple Island of Phineas Fletcher.*

1. Hamman describes the development and work of the Phipps dispensary, and gives statistics of results. The main function of the dispensary is held to be the prevention of the spread of the disease by means of popular education. In carrying this out much stress is laid upon the importance of the work of the nurses in securing continued adherence to the principles of treatment. A list of 700 patients is being visited. The effect of this in prophylaxis cannot fail to be great. Secondary to the prophylactic aims, but with increasing attention, the treatment of individual patients has been undertaken in a total of 1,474 cases, treated mainly by direction of the dispensary under supervision of the nurses. A small number were treated by the class method. The symptoms and results are briefly analyzed. Of 498 cases of pulmonary tuberculosis followed from eight to twenty-six months 16.4% are now improved, 14.3% unchanged, 18% worse and 51.27% dead.

2. Hazen has studied 83 families, of which one or more members were tuberculous, to obtain evidence as to the frequency of the transmission of infection to other members of the family. In two thirds of the cases a diseased parent had infected one or more children. Of cases where a husband or a wife had tuberculosis the consort developed the disease in 43%. Of the children exposed to parental infection 38% contracted tuberculosis. Of the 254 members of these families only three of those not in contact with their families developed the disease.

3. Hamman and Wolman discuss the diagnosis of pulmonary tuberculosis with special reference to the tuberculin reaction. They urge the greatest possible care in consideration of symptoms, physical signs and sputum examination, but in cases where these create suspicion, but fail to establish the presence of tuberculosis, they rely upon the diagnostic use of tuberculin, beginning with a dose of one fifth of a milligram, repeated three or four times, then doses of 1, 5, and 10 mgm.; temperature constitutional symptoms and local reaction manifested by changes in the local signs must be considered. A negative reaction gives positive proof of the absence of tuberculosis. A positive reaction must not be regarded conclusive, but is of value as a bit of evidence in addition to the symptoms and physical signs.

6. Bloodgood describes the condition of intestinal obstruction in two forms: strangulation ileus where in addition to obstruction there is interference with blood supply, and obturation ileus where the blood supply is not disturbed. In both of these surgical treatment should be applied, if possible, within the first twenty-four hours, but in the strangulated form there is special danger in delay. Fortunately, in this form the symptoms of onset are more acute and characteristic. The symptoms due to interference with circulation are pain (probably due to pull on the mesentery), peritoneal shock, and reflex vomiting. The obstructive symptoms, fecal vomiting and distention occur later and should not be waited for in diagnosis. The severity of the shock is greater than in appendicitis, gallstones or renal calculus, a point which is of value in diagnosis. The patient is pale with rapid pulse and feeling of weakness "as if he had keen kicked in the abdomen." The local tenderness and spasm of appendicitis and cholecystitis are absent, but there is a general rigidity of the abdominal muscles. Occasionally a distended loop of intestines can be palpated, externally or by vagina or rectum, and when this is present it is pathognomonic. Peristalsis may be made out in certain cases. A leukocytosis is constantly present. In obturation ileus the acute primary symptoms are frequently absent, but there is often a history of previous constipation and colic, and frequently of previous attacks of obstruction. Vomiting may be absent but the constipation and distention must be regarded as suspicious. Visible peristalsis is a constant early symptom where the small intestine is the seat of the obstruction, but the distention is much less than where the obstruction is lower. For the general practitioner it is to be emphasized that the diagnosis of any intestinal obstruction should be made early, and that cathartics by mouth and morphia are to be avoided; the stomach should be washed out and enemata given. In operation chloroform is the best anesthetic. In desperate cases a simple colostomy under cocaine is indicated. [F. W. P.]

1. Paterson, while admitting that both bile and pancreatic secretion must find their way into the stomach after the operation of gastro-jejunostomy, thinks that it is distinctly beneficial, and that some of the good results noted after this has been done for gastric ulcer are due to the alkaline fluid bathing the ulcer. There is also a marked diminution of the total acid secreted by the stomach, due not only to partial neutralization by the pancreatic fluid but to an actual decrease in the chlorides. He does not agree with many others who believe that gastric digestion is entirely done away with after this operation. Beneficial results after this operation are not due to drainage, but to the diminished acidity which allows healing of the ulcer. Many writers believe that such a radical change in the abdominal anatomy cannot be made without bad results on the metabolism. Paterson does not agree with this view, and reports experiments he has made confirming his theory.

3. Harrison gives a careful summary of the various views on the subject of mucous colitis. He dwells especially on the disorders of a more or less neurotic nature associated with it, such as asthma, disturbances of the female pelvic organs, and appendicitis. This latter may be part of the colitis, in which case operation will not cure the disease in the colon, or else it is a true appendicitis preceding the attack of colitis; in which case operation often relieves all symptoms. The evidence points to the conclusion that this disease is a pure neurosis, either secretory or motor. He goes over the symptomatology in detail, especially that cardinal symptom — pain. The patient should be kept in bed and carefully watched for some time. During the attack castor oil in large doses is indicated, enemata of various kinds and colon irrigations of warm water. In the intervals general measures to relieve the constipation, and to reduce all nervous irritation should be employed. [J. B. H.]

8. Power briefly considers the diseases of the testicle under the headings of tuberculosis, syphilis, teratomata, malignant disease, acute torsion of the cord, hydrocele and undescended testicle. In the latter case if the testicle lies in the femoral region or in the groin he invariably removes it. Howard goes over exactly the same ground in a similar way. Dixon considers the subject from the point of view of organo-therapy and discusses the literature of the subject of an internal secretion from the testes and its physiological effects. He believes that there is a very close physiological connection between the adrenal glands and the testes.

10. Nitch reports two cases of pneumococcic arthritis in children, and considers the subject in general. The prognosis is grave, the mortality being 50% in children. The treatment is essentially surgical, though vaccines in early cases should be tried.

15. Kelynack believes that pulmonary tuberculosis in children is far commoner than supposed, and deplores the lack of interest shown in this subject. He gives statistics of English examiners and Grancher's figures among Paris school children showing that 2% to 3% of children had open tuberculosis and 16% to 18% closed tuberculosis. The most important part of treatment is prophylactic. All children of tuberculous parents or who have been exposed to tuberculosis should have special surroundings and training; removal of these children from their homes into the country, forest schools, etc., are measures which should be imitated. France has 6,000 beds for consumptive children; England, 500. Special sanatoria are needed; those planned for adults will not do. He hopes soon to see established a national society for the study and care of tuberculous children. [J. B. H.]

1. Fischler has treated 15 cases of neuritis and neuralgia with Schlösser's method of alcohol injection. The injection is made directly into the nerve, 70% alcohol being used, and the place for injection being usually the point tenderest on pressure. Out of 12 cases of sciatica thus treated, 4 were completely cured, 4 much relieved, in 3 no relief was obtained, and in 1 case, though the pain was relieved, a complete paralysis of the deep peroneal nerve ensued; 3 cases of trigeminus neuralgia were cured. In 3 cases treated by Erb in his private practice, though pain was relieved, more or less complete paralysis followed the injections. The author concludes that while this procedure is often of great value, it is in many cases dangerous.

6. Fraenkel reports the case of a premature baby born

of a syphilitic mother, who five days after birth died, with symptoms of general peritonitis. The autopsy showed an old chronic peritonitis, which must have occurred during intra-uterine life, and a fresh purulent peritonitis. In the gut numerous small deep ulcers were found, which the author considers as the starting point of the peritoneal processes. Histological examination of the ulcerated areas revealed great numbers of the spirocheta pallida, occurring in the walls of the ulcer, in the capillaries of the submucosa, and in the muscular layers. In a zone about the ulcers the mucous glands of the mucosa were everywhere filled with spirochetes. Though no other manifestations of syphilis were to be demonstrated the author considers these ulcers to be of syphilitic origin. Such a condition is extremely rare. [R. D.]

6. COHN, M. *The Results of X-Ray Examination in Fracture of the Elbow.*

1. Meyer reviews the observations of Jolly and others on the appearance of functional and organic nervous disorders in the secondary and early tertiary stages of syphilis. He reports the results of careful examinations of 61 cases in the early secondary stage and 11 in the early tertiary. Out of 61, only 3 gave evidence of functional conditions developing after the infection; in 9, pre-existing functional disturbances were increased in intensity; in one half the cases a markedly increased irritability of the nervous system was to be demonstrated. Organic nerve lesions were found in only 5 out of the 61. Jolly's "Syphilitic neurasthenia" was not seen in any case. Out of the 11 patients with tertiary syphilis, in only 3 was organic disease of the nervous system found; in one a pre-existing hysteria had increased. The author concludes that early nerve disturbance, whether functional or organic, is extremely rare. In 30 syphilitics the spinal fluid was examined; 19 showed a more or less marked lymphocytosis, and 15 a pathologic albumin content. No connection between these findings and the clinical manifestations of nerve disorders could be discovered.

4. Myalgia and neuralgia are much abused terms, Peritz claims, also numerous cases of the above diseases pass unrecognized under the name of rheumatism, heart disease, etc. Though no pathologic changes can be demonstrated, each has a definite set of symptoms. Pain is the foremost complaint; in neuralgia it is referred to the nerve affected, occurs periodically, and is accompanied by tender points over the nerve. In myalgia, the pain is referred to a muscle, usually near its tendinous insertion, or at its thinnest part. Tender points occur also in myalgia, but are usually much larger than in neuralgia. A most characteristic symptom is, that over the affected muscle the skin is hyperesthetic to pin prick and to the faradic current. The introduction of a needle into the affected muscle, the skin being previously cocainized, causes acute pain. The author has found that 0.2% salt solution injected into the tender points of the muscle will usually relieve the pain. Many cases of simple "myalgia" over the precordia have led to a diagnosis of angina, pseudo-angina, or cardiac neurosis. [R. D.]

1. Forssner and Sjövall describe 2 very acute cases of poliomyelitis in which the most interesting finding is the occurrence of a very active phagocytosis by cells which invaded the ganglion cells. The ganglion cells appear to be injured, to degenerate, and then their remains are removed by a process of phagocytosis. This is a new observation in poliomyelitis, but the authors think that it is a common process which has hitherto escaped notice because the cases come to autopsy too late after the onset of the disease. They discuss also the problem as to whether the primary lesion is interstitial or parenchymatous and whether there is a causal relation between the two. They arrive at no very definite conclusion, but incline to the view that the interstitial is the earlier lesion and that the two arise independently from the same toxic cause.

2. Köster describes two cases of tumor of the spinal cord meninges almost solely from the point of view of symptomatology.

3. A detailed study of the temperature curves of infants to show the effect of vaccination. One hundred and fifty infants were studied and numerous illustrative temperature curves are given in this paper.

4. The report of one case of traumatic rupture of the spleen successfully operated upon, with a study of the blood changes over a period of two and one half months.

7. A detailed study of one case of cerebellar cyst with an extensive review and analysis of other reported cases.

9. This paper contains a detailed study of 22 cases of aortic aneurism.

10. Jacobaeus describes a case of a man of twenty who for three years had had a diffuse glandular swelling of one side of the neck with almost no constitutional symptoms. It was considered a case of pseudoleukemia and received x-ray treatment. After eleven exposures superficial ulceration developed. This slowly healed, leaving the glandular enlargement much less. Several months later marked splenic enlargement was noted. Exposure of the splenic region to the x-ray resulted in a marked decrease in size of spleen. Eventually the case died with symptoms of miliary tuberculosis of lungs and meninges. Autopsy and histologic examination showed a tubercular process in lymph glands, spleen, etc. Jacobaeus regards the case as primarily tuberculous. The good result of

x-ray treatment, contrary to the experience of many, he considers due to the fact that the tuberculous lesion was in large part a lymphocytic proliferation. Cases in which the change is mainly caseous or endothelial and connective tissue proliferation would be little affected by the x-ray, since its destructive action is chiefly on lymphocytes and leucocytes. This according to Jacobaeus explains the discrepant reports on the value of x-ray treatment in glandular tuberculosis.

13. Lennander and Nyström on a basis of 14 observed cases discuss peritonitis following enteritis. They distinguish the condition from septic peritonitis clinically by the much less marked constitutional and local symptoms. At operation they find sometimes purulent exudation, more often serous, which they believe in many cases to be either sterile or to contain very few bacteria. The lower intestine usually contains solid fecal matter, and some portion of the upper, varying in extent, shows congestion, hemorrhage and edema,— the primary local lesion. There is no demonstrable perforation. Many cases give no antecedent cause, others appear to follow dietary indiscretions. Prognosis is quite good after exploratory operation and exclusion of perforation or septic focus. After-treatment consists of rigid gastro-intestinal rest.

14. A single case is reported to show that the symptom-complex of Banti's disease may occur in conditions in which the pathological-anatomical changes in no wise resemble those described for Banti's disease. Syphilitic cases of this type have been reported. This case of Hedenius is interpreted to be a case of cirrhosis of the liver with very early, simple hyperplasia of the spleen. Hedenius thinks that the diagnosis Banti's disease should be carefully limited, and that at present it is undoubtedly too widely applied so as to include many cases that do not properly belong to this group.

16. Pettersson points out that very little attention has been paid to books as possible vehicles for the transmission of tuberculosis. Can tubercle bacilli be transmitted by books used by the tuberculous? He answers the question in the affirmative as the result of his investigations. He examined history sheets from a tuberculosis sanatorium by washing their surface with water and a brush and then sedimenting the water and examining the sediment microscopically. Of 10 histories examined 4 gave positive results. Of the 4 positive, 2 had lain on a table by the patient's bed, 2 had hung at the head of the bed. Of the 6 negative, 4 had lain on a table in the center of the room and 2 had hung at the head of the bed. There was no evidence that flies had served as carriers of the bacilli. Pettersson thinks that in coughing the bacilli are expelled in droplets of moisture (Flügge's Schleimtröpfchen theory) and so reach the sheets.

The larger part of this Festschrift consists of case reports, chiefly of neurological interest. They are not well adapted for review but the titles indicate fairly well their contents.

LETTER FROM LONDON.

[From our Special Correspondent.]

MONCKTON COPEMAN AND CANCER. THE HOSPITALS AND PHYSICAL REMEDIAL MEASURES. DR. DRESCHFELD.

LONDON, Sept. 4, 1907.

Mr. Editor: In 1905, Monckton Copeman, and Wilson Hake published in the *Lancet* the results of some determinations of the amount of physiologically active hydrochloric acid in the stomachs of normal mice and of mice suffering from cancer experimentally produced. Their estimations, which were made from stomach tissues plus contents, showed an *increase* of HCl, amounting in some cases to 50%, in the cancer cases, both where the tumor had ulcerated and where it had not. In a recent lecture these authors have offered some additional statistics, and remarks. They find that the increase of HCl is demonstrable in the stomach contents alone in almost the same degree as in tissues plus contents. Bashford explains the apparent divergence from the results of Benjamin Moore and others in human cancer, by suggesting that the increase corresponds to the needs of "mouse plus tumor" which often exceeds double the weight of a mouse alone; he draws a further deduction, *viz.*, that the conditions of growth of cancer are to be distinguished sharply from those of its origin. The investigators are now engaged upon the estimation of HCl in the stomachs of mice, the subjects of spontaneous cancer. Lazarus-Barlow does not consider that Jensen's tumor is a carcinoma at all, and Copeman admits that it is not biologically comparable. The lecturers naturally voiced the growing tendency to seek the conditions favorable to the origin and growth of cancer in disturbed metabolism; they correlate the observations of Moore as to the increased alkalinity of the blood-plasma in cancer and of Loeb as to the increase of cell growth, and the determination of pathological nuclear divisions in many of the lower organisms occasioned by increased alkalinity. Further, they call upon the work of Pawlow and Starling which has shown the extreme delicacy of the chemical relationship between the various digestive secretions, initiated by the gastric HCl, for an explanation of the cachexia and general bodily illness of many cancer patients. Copeman is making use of Metchnikoff's "lactic acid milk," the living bacilli of which rapidly supplant the normal bacterial inhabitants of the intestine, as a therapeutic measure. As a possible explanation of the action of trypsin in cancer Copeman suggests — basing his opinion on Fronin's observation that the injection of succus entericus induces a great flow of the intestinal juice — that the injection of the trypsin induces a flow of pancreatic juice which the deficiency of gastric HCl had hitherto left unstimulated, and that therefore great improvement of general body metabolism results and is quickly reflected in the cessation of growth, or actual retrogression observed in the tumor.

Hitherto, in London, we have left the exploitation of the fashionable methods of remedial gymnastics and physical exercises to quacks, for the most part; at any rate, we have had no departments in our large teaching hospitals either for the practice of the treatment or for the instruction of students. One of the many ill effects of this negligence has been that many, perhaps the majority of, practitioners do not know enough even of the technical terms of massage to be able to give proper instructions to a masseuse. Obviously, too, they cannot employ the measures to the full advantage, and it unfortunately results that a good deal of treatment is carried out apart from medical inspection at all. It is not that the staffs of the hospitals do not appreciate the possibilities and the scope of the treatment, but in most of the institutions considerations of space have precluded the organization of such departments. St. Thomas's Hospital has set the example, however, and the others will not be slow to follow.

By the death of Dr. Dreschfeld, of Manchester, the north of England loses perhaps the most distinguished of her physicians. Commencing life in this country with almost every handicap of physique, of speech (for in the early days his English was decidedly "broken") and of having to make his way as an "alien" in a city by no means free from a taint of bigotry, Dreschfeld attained not only financial prosperity, but also in an extraordinary degree the confidence, the admiration and the esteem of the profession in Manchester, in Great Britain, and in the wider field abroad. It is related of the time when he first entered Owen's College that he had to put up with a good deal of chaff from his fellow-students by reason of his foreign accent; the laugh was upon his side at the end of the first session when he carried off the prize for English.

His memory was prodigious, his reading encyclopedic, his industry enormous; distinguishing himself first as a physiologist, he secured the chair of pathology and later that of medicine in the University of Manchester. A first-rate clinician, a pathologist of great acumen and experience, a lecturer of great power despite a poor delivery, it is very hard to see where Manchester, already mourning the loss of Dr. "Tom" Harris within the last twelve months, will find a worthy successor to Professor Dreschfeld.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED OCT. 2, 1907.

MEAD, F. W., surgeon. Granted leave of absence for twenty-eight days from Sept. 10, 1907. Aug. 30, 1907.

BAHRENBURG, L. P. H., passed assistant surgeon. Granted leave of absence for seven days from Oct. 4, 1907, under paragraph 191, Service regulations.

LONG, J. D., passed assistant surgeon. Relieved from duty at San Francisco and directed to report to Passed Assistant Surgeon Rupert Blue for special temporary duty. Sept. 28, 1907.

CREEL, R. H., passed assistant surgeon. Leave of absence granted Passed Assistant Surgeon Creel in February, 1907, for one month, revoked.

BROOKS, S. P., acting assistant surgeon. Granted leave of absence for thirty days from Sept. 25, 1907. Sept. 27, 1907.

CURLEY, C. P., acting assistant surgeon. Granted leave of absence for eight days. Sept. 30, 1907.

DUNN, J., acting assistant surgeon. Granted leave of absence for thirty days from Oct. 8, 1907. Sept. 27, 1907.

HUME, LEA, acting assistant surgeon. Granted extension of leave of absence for nine days. Sept. 30, 1907.

MARSH, W. H., acting assistant surgeon. Granted leave of absence for ten days from Oct. 11, 1907. Sept. 27, 1907.

TUTTLE, JAY, acting assistant surgeon. Leave of absence granted Acting Assistant Surgeon Tuttle for sixteen days from Sept. 16, 1907, amended to be effective Oct. 3, 1907. Oct. 2, 1907.

THORNTON, M. J., acting assistant surgeon. Granted three days' leave of absence on account of sickness from Sept. 20, 1907, to Sept. 27, 1907.

THORNTON, M. J., acting assistant surgeon. Granted leave of absence for thirty days from Oct. 5, 1907. Oct. 2, 1907.

WELDON, W. A., acting assistant surgeon. Leave of absence granted Acting Assistant Surgeon Weldon for one month from Sept. 10, 1907, revoked. Sept. 30, 1907.

BOARDS CONVENED.

Under date of Sept. 28, 1907, boards of medical officers were convened, as follows, for the purpose of conducting medical examinations of candidates for appointment as cadet-engineer in the Revenue-Cutter Service, the examinations to be held Oct. 1, 1907:

At Newport News, Va., Assistant Surgeon G. L. Collins, Chairman; Acting Assistant Surgeon A. C. Jones, Recorder.

At Boston, Mass., Surgeon R. M. Woodward, Chairman; Assistant Surgeon T. W. Salmon, Recorder.

At Philadelphia, Pa., Surgeon J. M. Gassaway, Chairman; Passed Assistant Surgeon T. Clark, Recorder.

A board of medical officers was convened to meet at Baltimore, Md., Sept. 30, 1907, for the physical examination of an officer of the Revenue-Cutter Service. Detail for the Board: Surgeon L. L. Williams, Chairman; Passed Assistant Surgeon J. T. Burkhalter, Recorder. Sept. 28, 1907.

A board of medical officers was convened to meet at Chicago, Ill., Oct. 2, 1907, for the physical examination of candidates for appointment as cadets in the Revenue-Cutter Service. Detail for the Board: Surgeon G. B. Young, Chairman; Passed Assistant Surgeon B. S. Warren, Recorder. Sept. 28, 1907.

A board of medical officers was convened to meet at Cleveland, Ohio, Oct. 4, 1907, for the physical examination of an officer of the Revenue-Cutter Service. Detail for the Board: Passed Assistant Surgeon H. S. Mathewson, Chairman; Acting Assistant Surgeon W. A. Baird, Recorder. Oct. 2, 1907.

SOCIETY NOTICE.

THE NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — This Society will hold its regular meeting at Hotel Nottingham, Thursday, Oct. 17, 1907, at 7.30 P.M. Pediatric Section. Dr. Marion Nute, chairman. 1. (a) Dosage of Antitoxin and the Serum Reactions; (b) Some Unusual Sequelæ of Scarlet Fever. Dr. Mary S. Holmes, Worcester Isolation Hospital. 2. Observations on the Recent Problems of Infant Feeding. Dr. Edith Hale. 3. Report of a Case of Syphilis in an Infant Infected in Utero in Seventh Month. Dr. Marion Nute. General Discussion.

DR. BLANCHE A. DENIG, *Secretary*.

RECENT DEATHS.

JONATHAN JASON SMITH, M.D., M.M.S.S., died in Boston, Oct. 8, 1907, aged seventy years.

DR. VALENTINE MANAHAN, of Enfield, N. H., died Oct. 15, in that town, at the age of eighty-one. He was graduated from the Jefferson Medical College of Philadelphia, and was widely known throughout the state, in which he had practiced for upwards of fifty years.

BOOKS AND PAMPHLETS RECEIVED.

A Text-Book on the Practice of Medicine. For Students and Practitioners. By James Magoffin French, A.M., M.D. Third revised edition. Illustrated. New York: William Wood & Co. 1907.

Petite Chirurgie et Pratiques Spéciales Courantes. Par P. Souhèyran et P. Ardin-Delteil. Illustrated. Montpellier: Coulet et Fils. Paris: Masson et Cie. 1908.

Tropical Diseases. A Manual of the Diseases of Warm Climates. By Sir Patrick Manson, K.C.M.G., M.D., LL.D. (Aberd.). Fourth edition. Illustrated. New York: William Wood & Co. 1907.

The Pancreas. Its Surgery and Pathology. By A. W. Mayo Robson, D.Sc. (Leeds), F.R.C.S. (Eng.), and P. J. Cammidge, M.B. (Lond.), D.P.H. (Camb.). Illustrated. Philadelphia and London: W. B. Saunders Co. 1907.

Proceedings of the American Medico-Psychological Association at the Sixty-second Annual Meeting held in Boston, Mass., June 12-15, 1906.

A Graphic Method in Practical Dietetics. By Irving Fisher, Ph.D. Reprint.

A New Method for Indicating Food Values. By Irving Fisher. Reprint.

Transactions of the Maine Medical Association. Vol. XVI, Part I. 1907.

The Diagnosis and Treatment of Diseases of Women. By Harry Sturgeon Crossen, M.D. Illustrated. St. Louis: C. V. Mosby Medical Book and Publishing Co. 1907.

THE ROENTGEN RAY IN PEDIATRICS.*

BY THOMAS M. ROTCH, M.D., BOSTON.

ALTHOUGH the use of the Roentgen method has for some time been recognized as an important addition to our knowledge of disease, especially of the bones, yet its use in our routine work among children has been comparatively limited, especially in the so-called medical cases.

The value of the Roentgen method in children can best be tested by a systematic study of cases in the wards of a children's hospital, where each case can be kept under observation continually from the beginning to the end of the disease, and where all the other methods of diagnosis and treatment are at our command, in the hands of experts connected with the hospital equipment. In a hospital also there arises no question of expense to the patient or consent of the parents. The hospital physician is free to use his wards and the hospital facilities as a clinical laboratory, unbiased by anything but the good of the patient. Such a clinical laboratory, thoroughly equipped through the wisdom, liberality and humane foresight for accomplishing the greatest amount of benefit for the patients, has been placed at the command of the physicians and surgeons connected with the Children's Hospital by the managers, and it is my good fortune to have had rare opportunities for expert study in the medical wards under my charge. This opportunity has been greatly enhanced in value by the generous aid given me by my colleagues on both the surgical and the medical sides of the hospital, — aid which can only be appreciated when we consider how closely the diseases of young children are interwoven in medicine and in surgery, — beginning, perhaps, as a surgical trauma and ending with a general septicemia; beginning with a tubercular infection of the hip-joint and ending with terminal infection of the meninges; beginning with a pneumococcus infection of the lung and ending with an infection of the pleura or peritoneum; beginning with obscure pains in the joints, which would naturally make the parents think of rheumatism and so send for a physician, and ending with a rapidly developing osteomyelitis rendering operative interference imperative; beginning, again, with a subperiosteal hemorrhage, with symptoms such as would lead to surgical advice, and before the true scorbutic and medical aspect of the case has been recognized, terminating in destruction of bone and surrounding tissue.

For the complete study, then, of an individual child, a combination of expert medical, surgical, pathological, bacteriological and chemical knowledge is required, with all that a hospital gives in expert work on the blood, the spinal fluid, the feces, the urine, and, in young children, most important of all, the ear and naso-pharynx.

As one of the primary aids to diagnosis, and often alone determining the treatment in both medical and surgical cases, the Roentgen method of examination is rapidly taking its place, not only in rank with all the others, but in many cases proving the expert physical examinations to be wrong, and influencing the resulting lines of treatment to so great a degree that to diagnosticate and treat without this proof of the correctness of the diagnosis has in many cases proved to be foolhardy, dangerous and without excuse.

The knowledge obtained from the Roentgen ray, although at present confined to certain specific conditions, is continually widening; and it is well for the medical profession to recognize this fact and to assist in still further establishing its position among the instruments of precision to aid us, and in encouraging the perfection of its technic.

There are three chief objects to be borne in view if we are to make a systematic study of the Roentgen method among children. First, the technic should be carried out by experts who have been thoroughly trained for this work, and in whose hands a failure to make a successful plate is reduced to a minimum. The reason for this is that children are so restless and difficult to take that it is much more important than in adults to have the first plate successful. Experts, also, who understand the temperaments of children and possess the faculty of managing them quickly and successfully. This necessity can only be appreciated by watching the work as it is done in the Roentgenological laboratories of a children's hospital. Experts from long experience can make their work uniform by placing the tube at a uniform standard distance from the object taken, and the object in a uniform position and standard angle. This is especially necessary when we come to compare the normal anatomy of the part taken with disease of the same part, and emphasizes the fact that the use of the Roentgen apparatus in the hands of the practitioner in general almost invariably ends in imperfect and inexact results, and results which tend to throw discredit on the Roentgen method.

Second in importance is the full, intelligent and expert interpretation of the plate. Although this seems at first sight so simple, so easy to accomplish, namely, to look at a picture and see what one sees, yet in the present state of our knowledge the result, when a number of physicians are examining a plate, is liable to be as many opinions, as so often happens when a number of opinions are given on an obscure cardiac murmur. Even the expert has not begun to learn what can be seen and will be seen when the interpretation of plates in the future has been further developed by broader experience and by careful comparison with post-mortem findings. For the picture is there, and all that we have to learn is to determine the language and learn to read it. I have, for instance, had some Roentgenographs taken to determine the presence or absence of an infantile pyloric stenosis, and yet expert knowledge has failed as yet to read these plates, although the

* Read at the annual meeting of The Massachusetts Medical Society, June 12, 1907.

picture is directly and plainly before our eyes. We should then appreciate of what vast importance for future diagnosis is the perfection of interpretation. This can, of course, only be accomplished by those who are continually working, studying and devoting many hours a day to this work in a children's hospital, where a large number of cases can be kept under daily observation, and the clinical course and results of an especial case compared with plates showing the progress of the disease. Great progress can be made in this way in the interpretation of pleural and pericardial effusions, pulmonary solidifications and the rapid changes which are so common in the degrees of cardiac dilatation in young children.

So much impressed have I been, when following up my clinical examination, with the ever increasing expert interpretations of the same cases by the Roentgen method in the hands of Dr. Arial W. George, our hospital Roentgenologist, that I have become much shaken in the confidence which I formerly had that I was making a correct diagnosis by means of my physical examination. Cases of pericardial effusion, which would have been tapped but for the negative findings of the Roentgenograph, not infrequently arise, and these cases cannot all be accounted for by my individual incapacity and lack of skill in physical diagnosis, as in each case I have had as controls the opinions of other examiners whose knowledge and skill are acknowledged to be trustworthy. Of very great and unquestioned value, therefore, is the aid given now by technically good plates and expert interpretation; and of vast importance in the future, when this method of differential diagnosis is perfected, will be the routine use of the Roentgen ray in the hands of expert Roentgenologists.

The third object of importance to which I have alluded is a branch of special work which I have been engaged in during the past year at the Children's Hospital. This work is to give the normal living anatomy of infancy and childhood, showing the development of the organs and bones at successive periods, with short intervals as of months in infancy and with the intervals in childhood of a length which will be practically useful. Besides showing the changes taking place in all the organs during their growth by months and years they show us the changes so intimately connected with growth in height that it is only a wonder that a complete series of these changes was not tabulated long ago.

The bones in this series show at what age and period of development the centers of ossification and the epiphyses begin to develop, and the gradual increase until fully developed. The idea of the series is that, during the active period of development from infant to child and child to adult, there are so many varieties under normal conditions that it becomes exceedingly important to have pictures which shall show the different stages. For instance, it is not only necessary for intelligent diagnosis and treatment to recognize diseased conditions, but to be able to compare the diseased conditions of a certain age with those of normal development which would be present at that age. Such a series, as, for instance, in rachitis, enables the physician to recognize what conditions would be expected at certain stages of the disease by eliminating normal conditions; also the surgeon as to how far the normal conditions, according to the age, should aid in indicating when to operate and to what extent, by keeping in view such conditions. In order to show more clearly the ever-changing epiphyses and centers of ossification, I have had some of my plates reproduced for lantern pictures, but it must be understood that these pictures only represent an exceeding small number of the changes which I have found necessary to tabulate, in order that they can be of practical use to the practitioner, who at any time in a special case may need a particular stage of development to compare with the development of the age he is treating, for the purpose of exact diagnosis, and who will not be satisfied with too long intervals in the plates. It is also to be noted that the pictures on the plates are far more clear than are these reproductions.

Following out the idea of first having a series of normal anatomy to compare with diseased conditions of the same period of development, I have begun the series with the picture of a premature infant. In these normal pictures we have taken, as representing a normal condition, the average of a number of children who, according to a standard of normal external conditions, such as weight, height, development of the teeth, fontanelles and general health, could be taken as representing the normal condition at that age. In order to do this we need at least four or five pictures of the same normal external development to decide upon which picture would be most practical for the use of the physician and the surgeon, and this we have accomplished in this series.[1]

When we have become familiar with the living normal anatomy of the different parts at the different stages of development, we can, by knowing where to turn for reference in a complete series of plates, or by memorizing these plates, use them as letters of our alphabet, and can, with a proper interpretation of these plates, learn to recognize the living pathological anatomy of such cases.

The series of pictures which I have just shown are simply examples of what the series will represent when completed, for in the short time at my command it would be impossible to describe the many phases and daily changes which, in even a few cases, are needed to intelligently understand and treat a special case.

The Roentgen method of examination assists and does not replace other methods of examination. Over and over again, however, it corrects and controls an otherwise faulty diagnosis and makes possible a study of the living anatomy and pathology of the different periods of life. In pediatrics I have found it of inestimable value, for the wonderful recuperative power which exists

[1] When this paper was read I exhibited fifty lantern slides which, for want of space only, do not appear in this printed paper.

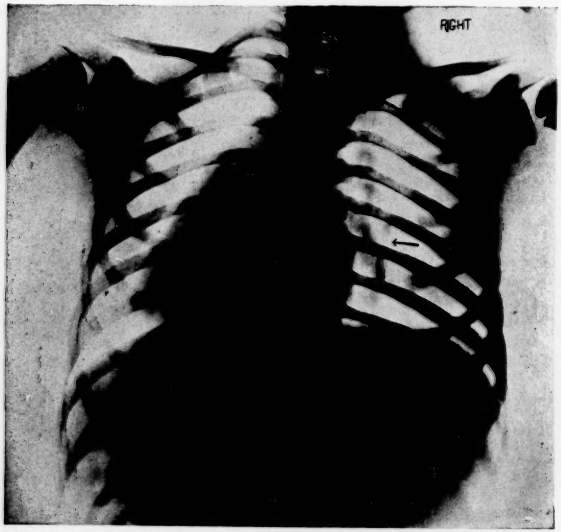

PLATE I. (A. W. George, M.D.)

CASE I. Case of enlarged bronchial glands, girl of twelve years. Notice dark shadows situated along right border of heart, extending up into apex. Seen in all normal chests, but to less extent than this. Lungs and pleura otherwise normal.

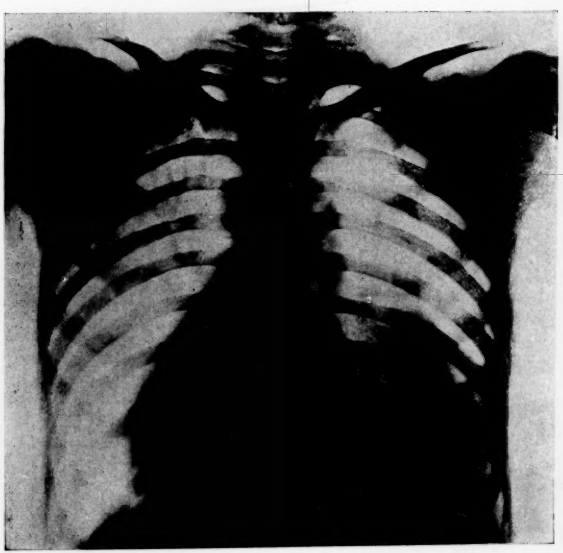

PLATE II. (A. W. George, M.D.

CASE II. Case of foreign body, nail, in lower lobe of right lung, boy of twelve years. Nail inhaled five years ago and not suspected then, as case was examined by Roentgen method, and foreign body not recognized. Treated since for various diseases of lungs and pleura. Roentgenograph shows nail surrounded by a dark shadow, indicating thickened pleura and collapsed lung. Operation not successful.

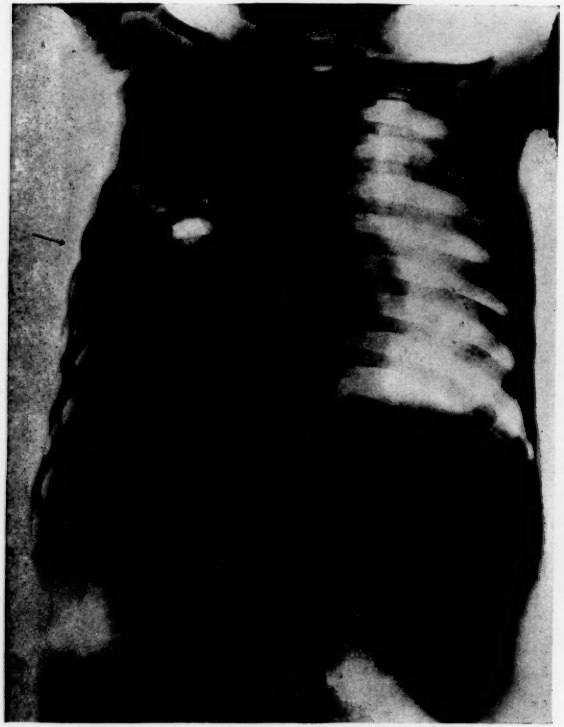

PLATE III. (A. W. George, M.D.)

CASE III. Case of plastic pleurisy in girl six years of age. Shadow extending over entire left chest excepting in central part. Shadow not changed with position.

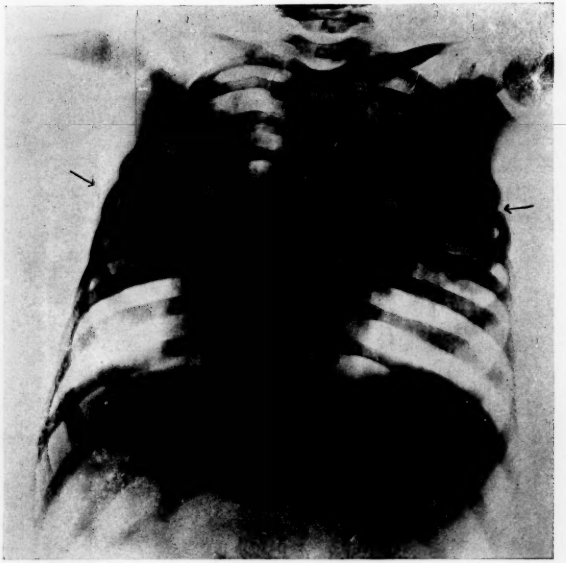

PLATE IV. (A. W. George, M.D.)

CASE IV. Case of acute miliary tuberculosis in girl of twelve years.

PLATE V. (A. W. George, M.D.)

CASE V. Case of pneumothorax in boy of nine years, taken a year after an attack of hydropneumothorax, showing the cardiac shadow displaced to right, and held there probably by adhesions; shadow of thickened pleura in lower left pleura. An area of either empyematous lung or cavity formation seen in central part of left lung.

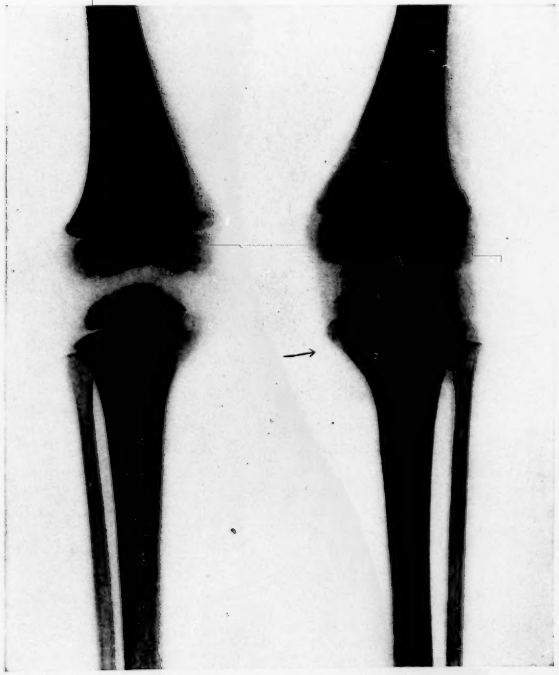

PLATE VI. (A. W. George, M.D.)

CASE VI. Case of osteomyelitis, boy of eight years. Process started in epiphyseal line of tibia. Operation delayed and process extended into epiphysis with destruction of bone and sequestrum formation. Capsule of joint thickened as seen by shadow.

PLATE VII. (A. W. George, M.D.)

CASE VI. After operation with bone plug in place. Plate demonstrates why operation was a failure. Sequestrum remaining behind plug.

PLATE VIII. (A. W. George, M.D.)

CASE VII. Case of villous arthritis in girl of thirteen years; capsule thickened and joint full of hypertrophic villi.

strates why operation was a failure. Sequestrum remaining behind plug.

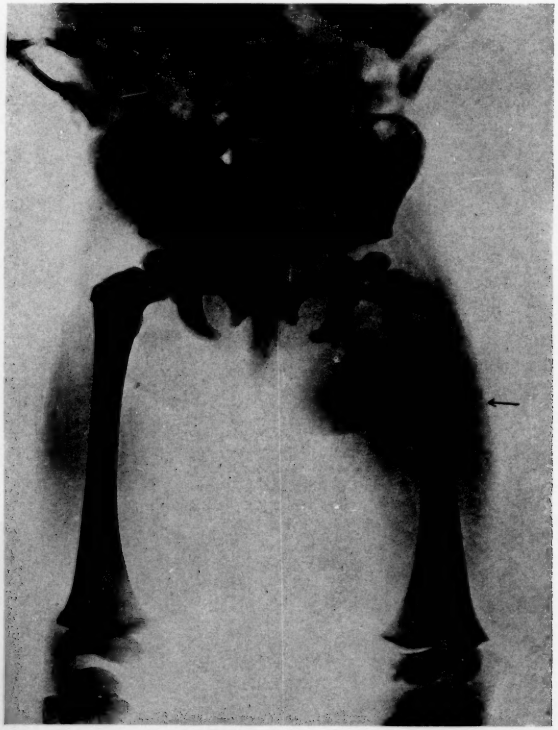

PLATE IX. (A. W. George, M.D.)

CASE IX. Case of acute infectious osteomyelitis in child of two and a half years, twelve hours after onset. Roentgenograph shows a haziness of the outline of the left femur with thickening about thigh. Process went on to general destruction of bone of the entire shaft of the femur. This (Plate IX) illustrates how early changes in tissues and bone can be demonstrated by the Roentgen ray; as early, in fact, as there are changes in tissue or bone.

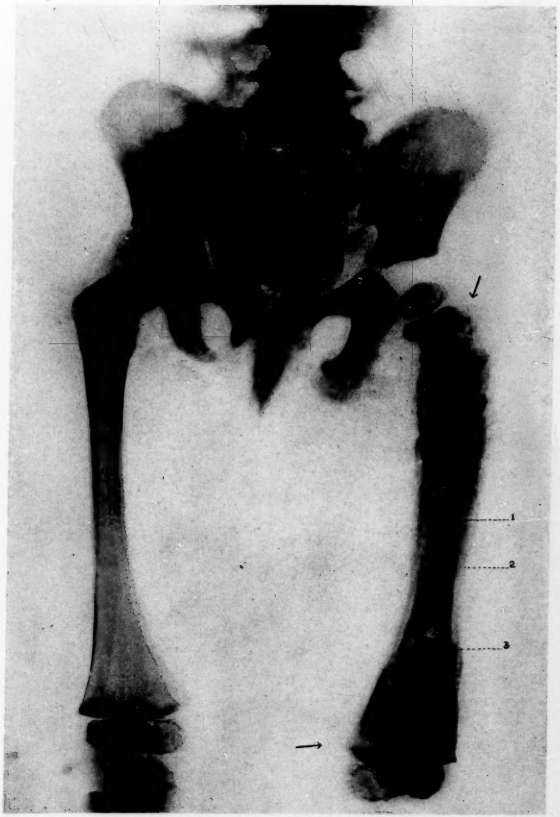

PLATE X. (A. W. George, M.D.)

CASE IX. Case IX five weeks later. 1. — Areas of suppuration. 2. — Newly-formed periosteal bone. 3. — Necrotic cortical bone. Arrows indicate point of attachment of capsule and periosteum to shaft of femur. Notice that joints have not as yet become diseased, and that infection of the bone is confined within the limits of the periosteum.

in children allows great opportunities for a varying treatment, if we can only follow the living, ever changing processes of the disease every few days. Used in this way for diagnosis, the Roentgen ray shows us the primary lesions of the disease, and for treatment therefore, the knowledge obtained by this method is far more important than a knowledge of the terminal lesions found at the post-mortem, especially as these latter lesions are often misleading as merely representing terminal destructive processes corresponding to the later stages of a number of different diseases.

REMARKS OF DR. ARIAL W. GEORGE, OF BOSTON.

There are certain points which should be noted in regard to the Roentgenology of children. In the first place the technic offers many more difficulties than that which is required in adults. What Dr. Rotch has referred to is especially important, that is, having the first plate taken successfully. Even though a child has submitted quietly when the first plate has been taken, it has become so restless from being restrained that it has been almost impossible to get a second plate, even if it comes on another day.

There are certain conditions which can only be diagnosticated by the Roentgen method. For instance, in normal conditions the epiphyses and centers of ossification are an unknown quantity until an examination has been made by the Roentgen method. In like manner small effusions in the pericardium, and very often the existence of thickened pleura, can be diagnosticated. In other conditions, although the Roentgen method is not the only one which will throw light on the disease, certainly a correct diagnosis cannot be made without it. The truth of this assertion is shown in the differential diagnosis of obscure cases of tuberculosis, osteomyelitis and syphilis.

What I have just said has not included those cases of foreign bodies, which can only be absolutely located by means of the Roentgen method. Also those cases of anomalous conditions of the organs and of the bones. Instance, the absence or imperfect development of the tarsal bones, the absence of ribs, or parts of ribs, and the numerical variations which at times arise in the spinal column.

A subject of especial interest has come to my notice through a fairly large experience in the Out-Patient Department of the Children's Hospital, — the injuries to the elbow joint in children. Very little is known at present about these injuries, and what knowledge we have of them is exceedingly imperfect. Yet the results of this lack of knowledge and the unfortunate results of improper treatment are manifest where such a series of injured elbow joints are followed up from beginning to end. The reputation of the surgeon who has charge of these cases will in a vast majority of instances be injured unless he avails himself of such conditions in the elbow as can be seen in the Roentgenograms.

The epiphyses are the most important centers of the skeleton, for on them depend its future development, epecially in infancy and childhood, and when these centers are impaired there results far-reaching influences in later life. A thorough knowledge of the different changes which take place in even this small area is very important, for these centers are where disease may begin, from which disease may disseminate, where it may lead to disastrous consequences and may leave its permanent marks.

Very little is known of the etiology of the diseases of nutrition and the especially important rachitic conditions which play such a great rôle in early life, and we also have a comparatively slight knowledge of its early stages. A more exact knowledge, obtained by the Roentgen ray, of the normal development of these parts, may lead to the recognition of more definite etiological facts regarding the disease and all other diseases connected with nutrition.

I have never yet found that the radiographs, however misleading they may be through imperfect interpretation, failed to represent a picture of what really exists. The Roentgen method will not demonstrate everything which exists in the body, but it certainly will not show that which does not exist.

In closing my remarks I should like to call your attention to how little regard is paid to the teaching of the Roentgen method of diagnosis in the medical schools. I am sure that great benefit would result from giving such teaching, for it would enable the student to understand the physical conditions existing in disease far better than he does now from simple physical examination of disease.

TWENTY-FIVE YEARS' EXPERIENCE IN THE TREATMENT OF STRICTURE OF THE URETHRA.*

BY FRANCIS S. WATSON, M.D., BOSTON.

WHAT I have to say upon this subject to-day is of a frankly personal nature, and relates in large measure to my own experience in the treatment of this malady and some of the lessons that I have learned in the course of the last twenty-five years, during which such cases have come under my care. For the sake of clearness and to enable you to follow my remarks more readily, I will state the points upon which I shall touch and the sequence in which they will be referred to, which is as follows:

1. The cases summarized in the form of a table which shows their total number, the nature of the process in which the strictures originated, the different methods of treatment to which they were submitted, and the mortality attending each of them respectively and of the total number as a whole.

2. An analysis of these cases with reference to the causes of death.

3. The character of the results of each of the different kinds of treatment.

* Read before the Massachusetts Medical Society, June 11, 1907.

4. The rules which must be observed in the performance of internal urethrotomy and the after-care of the operation.

5. The best manner of dealing with impermeable or very dense and extensive strictures of the perineal portion of the canal.

TABLE I.

	Cases.

Internal and external urethrotomy,	102	5	4.9%
External perineal urethrotomy alone,	56	5	8.9%
Combined suprapubic cystotomy and external perineal urethrotomy,	4	0	—
Partial resection,	4	0	—
Electrolysis,	13	0	—
Total,	580	13	2.2%

OPERATIVE MORTALITY.

Gradual dilatation is universally acknowledged to be the safest of all methods of treatment.

The mortality attending the operations of divulsion and internal urethrotomy is very small and is practically the same for both of the methods.

The high mortality which attends the performance of external perineal urethrotomy is to be referred to the critical conditions under which the operation is in many cases performed, and not to the procedure *per se*.

Electrolysis has about the same risk attaching to it as that which attends gradual dilatation.

The mortality of divulsion and of internal urethrotomy I have determined from a series of 1,000 cases of the former and nearly 5,000 of the latter, which I have collected from the literature.

The operative mortality of the series of cases in which divulsion was done was 2.1%. That shown in cases in which internal urethrotomy was done was 1.9%.

In my own series of 220 operations of internal urethrotomy in which that operation was performed alone, there were but two deaths, or less than 1% mortality, and I have never had a death follow the operation in private practice.

The mortality of external perineal urethrotomy I have computed from a series of 2,200 cases which I have collected from the literature and found it to be exactly 9%. My own mortality record is almost identical with that of this large number of cases, it being 8.9% in 56 cases in which I have done the operation alone.

CAUSES OF DEATH.

Deaths occurring in connection with any of the methods of treatment of stricture are, practically speaking, referable to one of two conditions.

1. Shock propagated from the peripheral nerves of the urethra and originating in the use of urethral instruments. One of the interesting features in this connection is the curious fact, which is true of both the constitutional disturbances and of the deaths which follow the use of urethral instruments, as in gradual dilatation for example, and which is, that neither the one nor the other of these untoward results is more likely to occur from shock, when violence and injury have occurred with the use of the instruments, than when they have been used with skill and gentleness.

In the cases in which deaths of this kind take place, the renal function is almost always suppressed. In most instances it is probable that the kidneys are already more or less diseased, but it is still an open question whether or no nervous impulses transmitted from the urethra or bladder in this way are capable of suppressing the function of a normal kidney.

The deaths of the kind of which I have just been speaking occur usually within a few hours following the use of urethral instruments.

2. Sepsis in one form or another accounts for almost all the other deaths which occur. In the cases in which so-called urinary infiltration is present, it is the already existing general septicemia which is responsible for the fatal result, and not the operation.

Much the larger number of deaths occur in this class of cases.

Death from sepsis is undoubtedly more likely to follow internal urethrotomy than other forms of treatment, if cleanliness and aseptic precautions are not observed in the performance of the operation. If they are, this ceases to be true and no further proof of the fact is needed than the very small mortality which appears in connection with the large number of operations which I have mentioned above.

As a matter of fact and everyday experience, a large contingent of the deaths is furnished by the employment of gradual dilatation by those who are unskilled in its use. This is because of the making of false passages by the rough use of the instruments and the opportunity thus afforded for the originating of septic processes which have their starting point in the false passages and the septic products which they harbor.

Gradual dilatation is therefore quite as dangerous a method of treatment as any other when it is not carried out by well trained hands. But few practitioners hesitate to use this method while they would not undertake the more definitely operative measures.

CHARACTER OF THE RESULTS OBTAINED BY THE DIFFERENT METHODS.

At the time at which I was a medical student one often heard the dictum, "Once a stricture, always a stricture"; in other words, it was regarded as an incurable malady. How little true this is to-day we shall see in a moment.

CURE.

By cure I mean that patients do not require to pass sounds subsequent to the operation or to the completion of the treatment, in order to maintain the normal caliber of the urethra.

My knowledge of the later results obtained by *gradual dilatation* by *internal* and by *external urethrotomy* is derived from my own experience, and that is the most accurate basis upon which to rest an opinion. Of *divulsion*, my own experience is not sufficient to enable me to speak authoritatively. I have therefore taken for the purpose of determining the final results of this method, the most favorable exhibition of them with which I am familiar, namely, the table of 27 cases out of a series of 404 operations performed at the Massachusetts General Hospital and published a number of years ago by Scudder. Before referring to these two methods, I will dispose in a few words of the results obtained by *gradual dilatation*, and *external urethrotomy* and electrolysis.

I have succeeded in curing but 10 out of 172 patients treated by gradual dilatation, that is to say just a little less than 6%, and in all 10 of these cases the strictures were in an early stage of formation.

Most of the 56 patients upon whom I have performed external urethrotomy alone were hospital patients and the larger number of them were lost sight of. Of the few that I have seen and examined since, but a small proportion have been cured, 10% perhaps.

When electrolysis was being vaunted as a method of treatment, a number of the members of the American Association of Genito-Urinary Surgeons gave it a fair and thorough trial. Personally I applied it in 13 cases. The unanimous verdict of all of us was that it was useless in all cases and harmful in some.

INTERNAL URETHROTOMY.

Of the whole number of 322 patients upon whom I performed the operation of internal urethrotomy alone, or in combination with external urethrotomy, there were 96 who furnished the opportunity to make subsequent examinations of the conditions of the urethra. In 22 of these cases less than two years had elapsed, when these examinations were made, since the operations were done, and I have not included them in the table. In 20 *others* the operation *failed*, in that the symptoms were not wholly relieved, or else that recontraction had taken place. In the remaining 54 cases, or 56% of the whole number, *cure* had resulted from the operations. The subjoined table gives in detail the calibers of the strictures at the time of the operation, the times at which the examinations were made subsequent to the operations, the sizes to which the strictures were cut by the operation and the calibers of the urethras throughout when examined later.

It is to be understood that sounds were not used in any of these cases subsequent to the opera-

tions except at intervals of a year or more for the purpose of examination.

The following are the data given in Scudder's table:

It will be seen from this table that there were but four patients who did not use sounds at all after the operations. Recontraction took place in all of the cases as follows:

To 26, 16, 13 and to a " very small size." That is to say, none of them can be called cured.

In 5 more of the cases the patients used sounds but a short time only, or at long intervals after the operations. In 3 of these cases no recontraction of any consequence took place, and they may properly be claimed as cures. In the other 2 cases recontraction to 26 and to 22 occurred.

The rest of the patients, 18 in number, all used sounds after the operations. Even so there were but 8 of them who succeeded in maintaining the urethral calibers at sizes varying from 26 to 30. Recontraction in various degrees (between 11 and 25) occurred in the other 10 cases despite the use of the sounds.

In other words, 11% of cures by divulsion as compared with 56% in internal urethrotomy.

With the exception of a very few English surgeons and a small number of the profession in this community who still practice, I believe, the operation of divulsion, it has been for many years universally relegated to the number of obsolete surgical procedures to which it properly belongs.

Why should the results of internal urethrotomy be better than those obtained by other forms of treatment, and why should not the cicatrix of an internal urethrotomy incision follow the law of other cicatrices and contract?

These questions have been renewed from time to time ever since Reybard, in 1853, presented in his treatise upon urethral stricture the results of his study of the cicatrization of *longitudinal* incisions in the urethra.

He showed conclusively that such wounds, if prevented from reuniting during the process of healing, result in smooth, thin, delicate and non-contractile cicatrices which add to the caliber of the urethra at the points occupied by them, instead of narrowing it.

The truth of this statement was confirmed for the first time by post-mortem examination, in the human subject by Perrin in 1865, in the case of a patient dying three years after an operation of internal urethrotomy performed upon a stricture of the bulbous portion of the canal.

Since then, other post-mortem proofs have accumulated, and a very large number of observations in the living subject by means of the endoscope and other instruments have established beyond dispute the correctness of Reybard's assertion.

Not long ago I had the opportunity of examining two patients upon whom I had performed internal urethrotomy twenty-two years previously. Both had had well-marked organic strictures. Neither of them had used sounds subsequent to the operations. The endoscope enabled me in one case to detect a very fine white line upon the roof of the urethra at the site of my former incision. In the other urethra I could find no evidence of any cut having been made. There was no sign of stricture in either case. Acorn tipped sounds failed to detect the slightest unevenness or constriction in either of them. In both cases a number 30 sound slipped perfectly easily into the bladder through the urethra.

It is evident why internal urethrotomy is the method of choice from a surgical point of view. Let me add, however, that this is true only with certain reservations, and only when the operation is done according to certain rules which will be specified in a moment.

Gradual dilatation remains, as has been said, the safest of the procedures. There are three reasons for it not being the form of treatment which is always applicable These are:

1. It is rarely curative. 2. It cannot be applied or it cannot be made effective in cases of impassable stricture, in such as are so resistent as not to yield to the pressure of the instruments introduced, and in such as recontract rapidly after the employment of the instruments used to dilate them — resilient strictures. 3. It is unwise to employ the treatment of dilatation when constitutional disturbances, chills, fever, etc., follow its use.

The cases which fall under one or another of these headings are numerous and all of them should be treated by internal urethrotomy. Upon one point I wish to lay special stress. It was insisted upon most wisely by Sir Henry Thompson, and is this: In the cases in which gradual dilatation is attended by constitutional disturbances, it is far safer to perform an internal or an external perineal urethrotomy than to continue the treatment by gradual dilatation.

I accentuate this because I know it to be true from experience, and because those who may be ignorant of the fact might well hesitate to adopt the seemingly more radical procedure of internal urethrotomy in the face of the occurrence of constitutional disturbance which had arisen in the course of gradual dilatation.

On the other hand, the following restrictions should be imposed upon the operation of internal urethrotomy.

1. It should not be applied to strictures further from the meatus than five inches. This is because of the greater danger of hemorrhage and of sepsis which occur when the incisions are made at a deeper point than this.

If external perineal urethrotomy is *combined* with internal urethrotomy, the latter operation can be performed as safely upon the strictures of the deep urethra as upon those of the anterior.

2. The operation is not as effective as external urethrotomy or resection in cases of very dense and extensive strictures of the perineal part of the canal and deeper.

RULES TO BE OBSERVED IN THE PERFORMANCE OF INTERNAL URETHROTOMY.

To be safe, and if it is to be successful in obtaining cure, the following rules must be strictly

observed in the performance of internal urethrotomy:

1. The urethra must be thoroughly irrigated immediately after the operation, after the first urination and after the first passage of sounds subsequent to the operation. The bladder should also be emptied and irrigated at the end of the operation.

2. The meatus must be cut to a size of 4 mm. larger than the normal caliber of the urethra.

3. The strictured part of the canal must be cut to the full size of the normal caliber of the urethra in each individual case.

4. The normal caliber should in each case be determined beforehand in accordance with the standard of measurements laid down by Otis.

5. The operation will fail if the urethra is acutely or subacutely inflamed at the time of its performance, or if such inflammation arises during the healing of the incision subsequently. The tying of a catheter into the urethra after the operation is objectionable because of the inflammatory reaction which it so frequently excites. When this occurs a greater amount of connective tissue is formed in the cicatrix and recontraction results.

6. The normal caliber of the urethra must be maintained during the healing of the incision, and this is secured by the passage of a sound of the size of the normal caliber of the urethra every second day after the operation until the wound is healed.

This requires on an average fourteen days. The absence of bleeding following the use of the sound is a reliable guide for determining when the incision has healed.

Otis's standards of urethral measurements.

The more important points connected with the standard of measurements laid down by Otis are these:

1. A constant relation exists between the circumference of the flaccid penis and the caliber of the urethra.

2. The penile circumference and urethral caliber vary in different individuals; consequently there is no such thing as one normal size for all urethras.

3. The average caliber of the normal urethra corresponds to No. 32 sound measured by the French scale. The penile circumference which corresponds to this is 3¼ inches. For every quarter of an inch of increase or decrease in the penile circumference there is a corresponding variation of 2 mm. in the caliber of the urethra.

This standard of measurements I, many years ago, confirmed by testing it in nearly 100 cases. I have not found a single instance in which it was not correct. Otis's standard is the only reliable, logical and accurate one that has ever been produced.

It is scarcely necessary to add that the size of the meatus is no guide to that of the urethra. The average size of the meatus is 24. A great many meatuses fall below this size, but few exceed 26. The meatus should be cut as the first step in the operation.

There remains a word to be said with regard to the best manner of dealing with the difficulties encountered in cases of impermeable stricture, and of treating those of unusual density and extent which are in the perineal part of the urethra.

With regard to the first I would say that there are but two ways which I think desirable to employ in order to trace or to make a road through an impassable stricture in the perineum.

The first of these is to perform a suprapubic cystotomy, pass a sound from within the bladder through the posterior urethra until it is arrested by the posterior face of the stricture. Next, pass another instrument from the meatus through the anterior urethra until it is arrested by the stricture. Now divide in the median line the strictures that intervene between the points of the two instruments and the road will have been safely opened.

The second way of accomplishing this result is by exposing the membranous urethra and the anterior end of the prostatic portion of it by the classic transperineal incision which extends in a forward arch in front of the anterior margin of the anus from one ischial tuberosity to the other, and by blunt dissection after dividing the median tendinous point of union of the structures of the perineum. The anterior bit of the prostatic urethra is then incised longitudinally, and as a rule a fine filiform bougie will readily pass from behind forward through the constricted part of the canal. Upon this instrument as a guide, the mass of connective tissues constituting the stricture is then divided.

Partial resection of the urethra. — The best method of treatment for the intractable strictures of the perineal portion of the canal which resist all the more usual means is by excision of the mass of connective tissue constituting the stricture. The results obtained by this method in such cases are better than can be secured in any other way.

Summarizing what has been said it may be put thus:

1. Electrolysis and divulsion are methods of treatment which should both be abandoned.

2. Internal urethrotomy is the only method of treatment by which an important number of cures can be obtained. It is an operation involving but little danger. Its application should be restricted to strictures within the first five inches of the canal unless external perineal urethrotomy is done in combination with it.

3. For strictures of the deeper part of the canal gradual dilatation is the best form of treatment if constitutional disturbance does not rise in connection with its employment, and if the urethra for a reasonable length of time maintains the caliber to which it has been expanded by the instruments.

4. For the cases in which the strictures of the deep urethra recontract rapidly after dilatation, or those in which constitutional disturbances arise in the course of its employment, also for the resistant or impassable strictures of the deep urethra, in all of which conditions gradual dilatation

is useless, external perineal urethrotomy, or internal urethrotomy combined with the external incision in the perineum is the safest and most efficient method of treatment.

5. External perineal urethrotomy is the only operation that should be applied in cases of stricture accompanied by urinary extravasation.

6. Resection of the strictured part of the canal should be selected in cases of intractable, very dense strictures of the perineal part of the canal.

Internal urethrotomy done under the conditions and in accordance with the rules I have stated above will yield from 50% to 60% of radical cures, and at an operative risk of death of about 1.5%.

DISCUSSION.

DR. J. C. MUNRO, of Boston: What Dr. Watson has said upon divulsion should be printed in large letters. I have never done the operation myself, and have always condemned it as most unsurgical. External urethrotomy has always been an operation of great interest to me, and some years ago I took occasion to look up my end results, and found that the deep urethra instead of contracting had become larger in caliber than normal.

I heartily agree with Dr. Watson in his views on the permanency of the results following gradual dilatation. This method has a very limited field of usefulness and should not be placed in the same class with urethrotomy. I personally feel very grateful to Dr. Watson for what he has taught me this afternoon, and wish to express to him my thanks.

DR. F. B. LUND, of Boston: I have been greatly interested in Dr. Watson's excellent presentation of this subject. We have at the City Hospital many cases of stricture of the urethra to treat, and we treat them all by urethrotomy; internal for the anterior strictures and external for the deep strictures. Internal urethrotomy as compared with divulsion is a scientific and accurate procedure instead of a violent and inaccurate one.

In a large number of external urethrotomies without a guide, which we are often compelled to perform in difficult deep strictures at the hospital, we are practically always successful, and I have only seen one case in the hands of a colleague in which the procedure of suprapubic cystotomy and retrograde catheterization had to be resorted to.

Many of our hospital cases belong to the class who neglect themselves after operation and consequently have to be operated upon a second or even a third time for reconstruction. It is in these recurrent cases, where the urethra is twisted and deformed by scar tissue, that the surgeon has the greatest difficulty, a difficulty, however, which patience will usually surmount.

I think that Dr. Watson's long experience in this class of cases enables him to speak with authority, and that his conclusions will be of great value to those privileged to hear or read his paper.

PROSTATECTOMY IN TWO STAGES BY SPECIAL TECHNIC.

BY FOLLEN CABOT, M.D., NEW YORK,
Attending Genito-Urinary Surgeon, City Hospital; Professor, Genito-Urinary Diseases, Post-Graduate Medical School and Hospital; Consulting Urologist to White Plains Hospital.

THE question of when and by what method to operate on middle age and old men suffering from prostatic obstruction is a difficult one to answer. No other problem in surgery requires more good judgment and skill.

There is no one method of operating to which all cases must fit. The patient's condition must be carefully considered and treatment instituted to meet the individual needs. A man may have a well developed senile hypertrophy of the prostate and yet be free from evidence of urinary obstruction. It is the position of the hypertrophy rather than its size which makes the trouble. While the rectal touch and the cystoscope are both of value in determining the amount and position of intravesical prostatic overgrowth, we must not depend upon these measures to the exclusion of others. The urinary distance, bladder tone and amount of residual urine should be carefully estimated. The presence of pain, of cystitis and other complications, — all should have consideration in determining the surgeon's decision. The general condition of the patient must be completely examined into and his arterial system, digestive organs and kidneys considered as to their probable resistance to surgical shock. Unfortunately, many prostatics do not reach the specialist until they are partial wrecks from long suffering and have become the victims of misguided kindness on the part of their physicians. In considering the question of treatment for a prostatic, his age, by itself, should not be considered of much importance. A man of seventy-five may be a much better risk as to resistive power than one of sixty-five.

In this paper I have under consideration sixty personal cases operated on in the past four years. I have divided them into three groups. Before referring to them in different groups, I will say that I do not believe it good treatment to allow a prostatic to become entirely dependent on the catheter. I find with few exceptions that this rule holds good. The catheter, however, may in certain cases be used to tide over occasional temporary attacks of retention, if the bladder tone is fairly well regained in a few days.

In another class of patients the catheter may be used once a day to empty the bladder and at the same time irrigate it with boric acid or a mild solution of silver nitrate. If, however, we find the residual urine is gradually increasing, or there is pain, spasm of bladder, hemorrhage or chills following use of the catheter, I advise early operation.

In my list of 60 prostatectomies, 33 were operated by perineal route with 1 death, and 27 by suprapubic, with 3 deaths. In spite of the lower mortality in the perineal cases, I have become convinced that in the majority of prostatics the suprapubic route is the one of choice. In my 33

cases the prostatic hypertrophy was fairly small and the patients were much better risks than the 27 done by the suprapubic route. I believe the urinary function and sexual power to be better preserved when the prostate is removed above the pubis.

I. Therefore, I now teach that no more than 20% of prostatic cases, and those with a small growth easily reached by rectal touch and without apparent complications, are suited to the perineal operation.

II. While the remaining 80% of the cases are best adapted to the supra-enucleation, many of these, owing to complications and debility, will not survive a complete prostatectomy by any route.

III. What shall we do with this debilitated and emergency class of probably 40% of all prostatics, — the cases which make us doubtful as to their standing more than mild surgical shock and yet where something of a surgical nature is necessary?

Lilienthal, of New York, answered this question in 1896, by performing preliminary cystotomy by suprapubic route; draining till the patient was up and about, then through the same cut enucleating the prostate. To my mind this method is one of great value, and from my own experience with it, I believe it will be used more and more as its merits are better understood.

In performing this two-stage operation by special technic of my own, I always use the suprapubic route.

My reasons for this are that the field of operation can be more closely watched during and after operation than can the perineal one. This is a matter of importance when loss of blood has to be carefully prevented and slough watched for later on. The size of the prostate and general condition of the bladder can better be determined; for instance, stone discovered loose or in a pocket; also new growth found which might have otherwise been overlooked, even when the cystoscope has been used; and, finally, enucleation more quickly performed than by perineal route, and the drainage tube much more comfortably placed for the patient when he is up and moving about between the two operations.

The following case, in which I performed enucleation in two stages, typifies what I have already said. I have no doubt that this patient would have succumbed to any prostatectomy if it had been performed in one stage. As it was, he weathered two little blows given with an interval between them for recuperation, instead of going under to one big blow delivered when he was weak and unprepared to resist it.

This patient, the relative of a prominent New York physician, was operated on in December, 1906. He was seventy-five years old and had been suffering from symptoms of prostatic obstruction for twenty-five years. General condition was bad; irregular heart; well-marked arteriosclerosis. Digestive system in fairly good condition. Some albumin and few casts in urine showing evidence of renal irritation as result of back pressure. Very severe cystitis, alkaline urine with well-marked ammoniacal decomposition. Urinating 6 or 7 times at night and each hour or less in day till catheter life was begun shortly before I saw him. Residual urine, 14 oz. Urinary distance somewhat increased and prostate, by rectal touch, high up and difficult to reach. It was apparently not very large and felt smooth and firm. Recently he has complained of chills and has reacted badly to bladder irrigation. Never has passed much blood. Owing to the patient's enfeebled condition and severe cystitis it seemed best to operate by two stages, and so I performed a suprapubic cystotomy under light chloroform anesthesia, it being thought best not to give gas. The bladder was opened under air dilatation and a tube of 44 French caliber introduced. The prostate and bladder were also carefully palpated, all of which took eight minutes. The third lobe or isthmus was hypertrophied and caused the difficulty. The rubber drainage tube was secured in place with a Bangs shield and the patient was put to bed. The old gentleman quickly recovered from the anesthesia. Strych. sulph. gr. 1–30 each three hours was administered, also small quantities of soft, uncharged water were soon taken at frequent intervals. The latter was given to stimulate the kidneys. While the pulse never went over 100 and the temperature remained at about 99.5°, there was considerable prostration the following day. However, in forty-eight hours the patient rallied well, and on the third day sat in a chair for an hour or two. Bladder was washed frequently with boric acid and saline solution. Cystitis gradually improved with addition of urinary antiseptics and acids to correct alkaline reaction. In about two weeks the patient was walking about and going downstairs to his meals. At the end of three weeks the urine was clear and free from albumin. He then was in much better condition than he had been for several years. I then, without telling him that the operation had not been finished, operated again through same cut under chloroform, and in nine minutes removed the prostate. During the enucleation a catheter was introduced through the penis, hot saline solution was continually run into bladder and at the end of the operation several ounces of solution of adrenalin 1–3000 was introduced. Very small amount of hemorrhage. The congestion about the prostate had disappeared during the period of rest and so there was less blood in and about the gland. The enucleation was carried out so that the whole prostate was removed in one piece. The prostatic capsule was packed with a strip of gauze which had been soaked in adrenalin 1–3000. The urethral catheter was left in place behind the packing to use for adrenalin in case of hemorrhage and later, after gauze was removed at end of forty-eight hours, for inlet to irrigation. The large tube in the suprapubic wound was for outlet to fluids. The patient seemed to have less prostration following this final operation than he did from the preliminary one. I attribute this fact to his improved condition as a result of good drainage of bladder, rest and nursing for three weeks. In three days he was up and at the end of seven days both tubes were removed. During the healing of wound a small catheter was daily passed into the bladder through wound and the cavity irrigated. In fourteen days the wound had completely closed and the patient was soon passing urine in a very satisfactory manner. The control was good from the first, as it usually is when the operation is performed suprapubically. After this time no further irrigation was employed and no urethral sounds passed at any time. It does not as a rule seem to be necessary unless there is some complicating condition in the urethra which needs it. Stricture, however, in my experience, is rare in prostatics. This

month, June, patient reports himself in fine condition, is back at work, has no urinary symptoms, empties his bladder completely and feels better than he has for twenty-five years.

While all cases do not do as well as this one, the advantages of the two-stage operation are clearly shown. In some of my more recent cases I have performed a preliminary cystotomy under local anesthesia and then at the same sitting, if the patient's condition warranted it, given a little chloroform and removed the prostate. This enucleation should not consume more than ten and frequently only five to six minutes. In one case I did the whole operation under local anesthesia and the patient complained of little pain. In subjects with very fat abdominal walls, local anesthesia is difficult or sometimes not practicable at all. I believe though that, in future, I shall open the bladder under local anesthesia in all the cases in which I find it practicable. Fortunately few prostatics are very fat, so that it can be done in most instances. Then, if I do not believe it wise to do more, drain till the patient's condition warrants further interference. This is a new way of using the two-stage operation and is readily adapted for a different class of individuals than given in the history of the one above. I am also convinced that ether anesthesia is the cause of many deaths in prostatics from kidney and lung complications following operation, and so never use it. Again, if we avoid general anesthesia of any kind for half the operation, we are saving the patient a great deal. The nervous element, of course, has to be considered, but I have seen no ill effects from the local anesthesia. I agree with Fuller that opium or any of its alkaloids should not be given, as they injure the patient's chance of recovery, by lowering his vitality and preventing proper renal action. I, therefore, never use them.

I present the following conclusions:

1. In the event of any question of the patient's physical condition being equal to a complete prostatectomy, do a preliminary suprapubic cystotomy under local anesthesia. This will probably be the operation of choice in 50% of the cases. Drain the bladder while the patient is up and about, till the condition is better than before cystotomy. This will take from ten days to four weeks.

2. In all cases with severe cystitis, damaged kidneys in cases suffering with severe hemorrhages, in all so-called emergency prostatectomies, and in diabetics, carry out this preliminary cystotomy and later, as the patient's condition warrants it, do an enucleation.

3. Its advantages are the quick relief afforded with slight shock from severe symptoms. We give a patient all the advantages of a prostatectomy, with none of the serious dangers. He gets good bladder drainage and consequent rest and comfort.

4. If the preliminary cystotomy kills, a prostatectomy would have been foolhardy. If the patient recovers from the little blow he usually rapidly gains strength; the prostate becomes less congested; the cystitis disappears and we have produced a change which usually permits a successful enucleation later.

5. At the time of this second operation, well developed granulation tissue has appeared and prevents absorption.

6. At each operation we have only one point of hemorrhage to look out for instead of two, as is the case in a complete operation at one time. This is of importance in feeble old men, and should not be overlooked. My special way of controlling prostatic bleeding is of distinct advantage and would better be used in all cases.

7. The final operation should never be performed till the patient's condition is better than it was before the preliminary cystotomy.

8. The ease with which these feeble old men become bedridden is a danger, and therefore the fact that they can be gotten up so quickly after the preliminary and final operations adds much to their chances of recovery.

Their proneness to contract pneumonia and other diseases while lying in bed is well known, and we diminish this danger by getting them on their feet in a few days. This is a much more difficult matter in the severe shock following a one-stage operation.

THE QUESTION OF "JUSTIFIABLE HOMICIDE."

BY CHARLES GREENE CUMSTON, M.D., BOSTON.

(Concluded from No. 16, p. 531.)

CHATEAUBRAND thus relates that in his youth he was surrounded only by the women of his family, but he became amorous for a woman who only existed in his imagination. "*Je me composai donc une femme de toutes les femmes que j'avais vues: elle avait la taille, les cheveux et le sourire de l'étrangère qui m'avait pressé dans son sein; je lui donnai les yeux de telle jeune fille du village, la fraicheur de telle autre. Les portraits des grandes dames du temps de Francois I, de Henri IV et de Louis IV dont le salon était orné, m'avaient fourni d'autres traits, et j'avais dérobé des graces jusqu'aux tableaux des Vierges suspendus dans les églises. . . .*"

"*Un seul de ses regards m'eut fait voler au bout de la terre; quel désert ne m'eut suffi avec elle! A ses côtés, l'antre des lions se fut changé en palais, et des millions de siècles eussent été trop courts pour épuiser les feux dont je me sentais embrasé.*"

Later when he was exiled in England, he became extremely amorous of a young girl, because he found in her a resemblance to his former ideal, but, being married, he was fully aware of the inanity of his passion. If such is the passion in healthy minded men, what can it be in those who, on account of their family antecedents, or a nervous nature, are subjects of predilection for all mental diseases? They are in need of a particularly rigorous moral hygiene, and, on the contrary, I have endeavored to show that, during all their life, this feverish nature has been developed from their surroundings and the

character of their life. Consequently, one can hardly conceive of the intensity of these passions beyond which nothing else exists; they are a physical torture and, at the same time, a moral pain.

In studying the character of the criminal from passion we have seen the latent and deep causes of the crime, those which are the nearest to human nature and which, consequently, are the most difficult to reach. The occasional causes, on the contrary, those which furnish the circumstances to the subject which will cause him to commit his crime, are possible to modify, although this is a difficult undertaking. In the first place, the general causes which influence criminality are to be considered, and afterwards certain causes which pertain strictly to crimes from passion. We will merely mention the principal causes of criminality, making note of those which may exercise an influence over passionary crimes.

In the first place alcoholism has, as is well known, a very great influence on this class of crime. It often happens that it is during alcoholic intoxication that the jealousy of the man of the people breaks out, and the continued use of alcohol renders the character violent and irritable, and for this very reason predisposes the subject to acts of violence and vengeance.

I have also pointed out the influence of heredity and insanity upon crimes from passion. In the moral point of view one should note that the passionate subject does not lack moral sense in a general way, like the ordinary criminal, but that occasionally he is wanting in it as far as the special point of vengeance is concerned, and he considers the latter as an act of justice. As to imitation, the passionary criminal appears to be subject to the same rules as other criminals. One not only often meets with instances of repetition of the same kind, but occasionally one can distinctly see a copy in a passionary crime even including the details of another crime which has been committed shortly before by another person. For this reason one cannot underrate the dangers incurred by the detailed accounts of crimes in the newspapers and the bloody pictures that they place daily under the eyes of their readers who, unfortunately, are only too avid for these accounts.

A certain influence may be attributed to the climate and, generally speaking, it may be said that these crimes are more frequent in warm countries than in temperate ones; and lastly we would note that misery, ignorance, great political crises, are without any influence whatsoever on the criminal from passion.

Beside these causes of a general order, which have an influence on all criminality, one should rank the causes which are peculiar to crimes from passion. Leaving aside the culpability of their authors, these crimes are the consequence of the mistakes of people, of the law or of public opinion. A large part of the responsibility is incumbent upon public opinion, which encourages the seducer by its indulgence, if not even by its admiration. It is this same public opinion which directs the education of woman and gives her a tendency especially to the art of seduction and coquetry, thus rendering her far easier to seduce than seducing. And, lastly, it upholds the laws which insufficiently protect young women excepting to cause her to carry her fault in disgrace.

A part of the responsibility of a crime from passion is often incumbent upon the victim. Ordinarily what makes the murderer so interesting is the little interest that his victim inspires to honest people. There is evidently no proportion between the offense and the vengeance, but either he or she who has only been the victim is extremely badly placed to appreciate the greatness of the offense received. The seducer generally does not take into consideration the extent of his responsibility and always says that he has merely done like others, and he was protected by public opinion up to the day of the scandal. Morals have diligently taught him that to seduce a young girl and leave her afterwards is to dishonor her, to morally assassinate her, and that a man should marry the virgin that he has possessed, but customs and the law speak in a different tone.

It, however, is not enough for a man to ask, it is necessary that the young girl give herself up to him, and a question arises whether or not she is not quite as responsible, having given up all that her fall will bring upon her. Most assuredly there is certainly much truth in this objection; but, just as we admitted that a portion of the responsibility of the seducer is incumbent upon public opinion and the laws which protect and cover him, so one must recognize that woman, especially in the working classes, is prepared for the seduction by everything which surrounds her.

In the first place her education is bad. In all large cities young girls of the people are in a condition much superior to the men of their own class, in their dress, their external appearance and even mentally. They thus become the easy conquest of men of the easy class, and there would be fewer girls seduced and less adultery among married women if parents did not give their daughters habits of luxury superior to their fortune and their social rank. It is also to be remarked that at the present time the form of work has greatly facilitated seduction. Formerly workmen and their wives worked at the common home, the children also, and thus they all had a hearthstone around which they remained united. Now machinery, the large department stores and workshops have called them out of their homes, and there is a decrease in the morality which naturally follows this splitting up of families.

In the well-to-do classt he education of young girls is almost entirely directed towards everything that can render her seductive, and it would even appear that the instruction she receives merely adds to the possibility of her seduction. The jests, actions and words that she acquires are those which appear eminently suited to please, and all this tends to exasperate her coquettishness and simply goes to show that her education has for its ultimate attainment the conquest of a husband. Then marriage comes and the

woman has from this time on less use for her brilliant qualities and must, on the contrary, search the more severe ones of marriage.

Outside of education and coming back to the popular class, there is another cause which may force the woman onward to her fall, namely, the general insufficiency of the salary paid to girls.

To sum up, it must be admitted that the nature and education tend to draw women into a trap, into which they fall easily when the solicitations of a man are sufficiently pressing, and the need of money weakens her resistance still more. To resist all these temptations a woman must possess a very great moral force, and she must also be able to resign herself to her condition. Now, in point of fact, religious sentiment has very greatly diminished in the popular class, and in all classes, for that matter, within the last century. During the epochs of faith, in order to cause disorder, it was necessary to truly love; to violate the general laws one was obliged to make great sacrifices. It not only meant to face fortuitous dangers and to brave the laws, but one was obliged to vanquish in himself the empire of regular habits, the authority of the family, the tyranny of domestic customs, the opposition of the conscience and the terrors and the duties of the Christian.

We do not pretend to study the consequences of the disappearance of religious beliefs, but, from the standpoint of the question which we are considering, we should place aside two of its consequences, namely, the absence of resignation and the desire of an immediate personal benefit. It is quite certain that morals deprived of sanction cannot become popular, and that by losing the belief in a higher life the great mass of people have lost the sense of the moral itself.

The conduct of a young girl whose poverty prevents her marriage thus becomes a question of an interest well understood and is no longer a moral one. She will argue that it is just as well to have as much fun as possible during her young days, if nothing but age and infirmity are to follow. On the other hand the conception of marriage as the only possible union has also disappeared from the large majority of minds, and marriage has ceased to be a sacrament and has become a contract, which itself becomes every day more fragile under the influence of public opinion, law, and the jurisprudence in matters of divorce. The customs having rendered the fall of woman an easier and a more frequent matter, has law increased her protection?

In every instance where a misdemeanor is easy to commit the law should redouble its severity in order to do away with those who profit by this facility and, consequently, it should be severe for the seducer, especially severe for him who abuses the young girl by promising her marriage and abandoning her as soon as she becomes a mother.

Unfortunately, this, however, is not the case, and there is a certain Pharisaism to defend the search of paternity in the name of the family and morals.

This does not mean that the seduced girl's crime is legitimate, and if this crime was merely caused by some defect of the law, it would nevertheless be an immoral act and absolutely antisocial, because it is a crime and not an act of justice, and, on the other hand, the punishment inflicted upon the seducer is quite out of proportion to his crime. It is as much as wishing to proclaim the right of vengeance to the seduced girl, and this has most seriously compromised her cause and it has been discredited by a certain party of public opinion. It has been thought that the acquittals of juries practically proclaimed this right, when in reality they merely wished to give proof of an extreme indulgence that they had for the cause, because there are no punishments of a special nature for the passionary crime.

However, the mistakes of legislation have had an undoubted influence on criminality, and there is a sociologic law which may thus be defined; in every instance where, on account of an absence of legislation, the individual is not sufficiently protected, he will always have a tendency to mete out justice himself. Thus, for example, the law does not allow a suit to be brought for a gambling debt, and consequently society and customs have considered these debts as privileged, or ones of honor, and public opinion is far more rigorous for those who do not pay them than for the debtors against whom creditors are armed. It is, however, in cases of insult made to a person that the fact is most evident. It is quite certain that individual property is much better protected by the law than the human being. Thus the law renders hardly any satisfaction in the case of a person outraged in his honor and so forth; the consequence has been that the individual substitutes himself for the law and avenges his honor himself. What satisfaction could a man, who has received a slap in the face, obtain from justice? The defamation is also insufficiently punished, and here again the individual will mete out the justice himself. When he cannot or will not do it by resorting to duelling it is by a murder that he accomplishes his vengeance. The law does not protect sufficiently the honor of the young girl or of the husband, and here again feeling that they are not sufficiently protected they have been desirous of carrying out justice in their own way.

In France, at least, there seems to be a change for the better in the legislation, and in January, 1904, the civil court of the Seine accorded, as an indemnity to a seduced girl, a pension that her lover in reality owed her in his quality as father.

A young woman, abandoned with two children, claimed a yearly indemnity in order to bring up the children that she had had by him during several years of cohabitation. She proved that, during the entire time of their false marriage, he had conducted himself as a father towards her children, and, although he had not entered into any formal contract, he had given her to understand that she could rely upon him. The Court condemned the physician to pay his former mistress eight hundred francs income a year until the majority of the children, the decision handed down by the learned judge being as follows:

"Since it has been proven that up to within very recently the defendant has contributed in a certain measure to the support of the children; since it has been shown by the written correspondence produced in the trial coming from the defendant and constituting the commencement of a written proof, that from an *ensemble* of grave, precise and concordant presumptions that he engaged himself to be responsible for a portion of the aforementioned expenses," etc.

Relative to the husband, jurisprudence has been less fortunate, since it has diminished the sentence of adultery so as to make it almost purely theoretical. When a husband brings a divorce on the charge of adultery before the Courts and presents himself at the trial as a witness, he submits to a very trying position, but at least he hopes to be avenged. If society simply accords him a derisive satisfaction, it is to be feared that he might be desirous of adding his vengeance to that of society, and it is more especially to be feared that others will scoff at such a meagre satisfaction in order to render justice themselves.

Mistakes in legislation have always existed, but why should it be that in modern times the consequences of these mistakes should be murder? In the first place these *lacunæ* in the law have not always existed in the same manner. In former times a young woman of quality was far more protected than the modern young woman, from the fact that, shut up in a convent until her marriage, she remained a stranger to daily life. The mistake of a young girl in the eighteenth century, for example, the mistake of a young girl well born, especially, was of an extreme rarity. For that matter seduction is not a gain; far from it; and its consequences would cause one to seriously reflect and make the most amorous very tepid in their desires. In 1737, M. de la Roche-Courbon was condemned to have his head cut off for having seduced Mlle. de Moras in the convent of Notre Dame de la Consolation. Her mother died from a broken heart and he himself fled and, driven out of Sardinia, where he had taken refuge at the house of one of his relatives, M. de Senneterre, the French Ambassador, finished his days miserably. The curate who had given the pair the nuptial benediction was placed in the galleys; the chambermaid of Mlle. de Moras to be whipped, to be branded with the fleur de lys and to nine years' banishment.

Formerly, the husband was not less well armed, although he employed his arms less freely. Ordinarily tolerant, especially during the eighteenth century, the husband shook off his indifference occasionally, wounded less by a sudden jealousy than by the humiliation which the wicked tastes of his wife caused him. Consequently, the older laws gave very severe punishment in cases of adultery between a woman of condition and a man of the people. Muyart de Vouglans mentions a sentence rendered by the Parliament of Paris which condemned a valet to be hanged for having committed the crime of adultery with his mistress, "*quoique celle-ci lui eut donne occasion en se decouvrant immodestement devant lui.*" Fournil mentions the case of a woman of condition, who, taken by surprise in the act of adultery with a car driver, was condemned to be hung, as well as her accomplice, in 1567. Bruneau, another jurisconsult, quotes the case of a wife of a magistrate who was caught in the act of adultery with her servant, and another of the same condition with her husband's clerk, and in both cases the same sentence was handed down. Adultery was in these days reprimanded, not merely with severity, but with cruelty.

During the eighteenth century customs became milder, husbands likewise, and nevertheless when one of them wished to avenge himself the powers given him by law were certainly immense. The wife was taken from her bed in the morning and thrown in a carriage which was drawn under the escort of four armed men and conducted to the Convent du Bon-Pasteur, which was a kind of house of correction. Oftentimes the wife was even taken away during a banquet, brutally snatched away from some pleasure, like, for example, Madame de Stainville, the foolish lover of Clairval, who was seized with all her fineries in the midst of the rehearsal for a ball to be given by the Duchess de Mirepoix; she was separated from her women, her confidential maid was locked up at Sainte-Pelagie and she herself was taken to the sisters of Sainte-Marie at Nancy. Many other notable seizures and imprisonments could be mentioned, but space forbids. These imprisonments of an unfaithful wife in a cloister were the right of the husband during the eighteenth century and he had in his hand these sudden and fearful punishments. In the midst of a relaxation in the morals and of all the complaisance of the society for scandal, he remained armed by the law. A sealed letter, obtained upon the proof of adultery, was sufficient to give him power to place his wife in a convent to the end of her days, if he so chose. Occasionally, having recourse to justice, he had her condemned to two years in the convent, during which he retained the liberty to visit her or take her back, if he chose. When the two years had elapsed the wife was condemned to be shaven and imprisoned in the convent for the remainder of her days if the husband took no steps for reclaiming her.

It must, however, be said that the husbands rarely resorted to the power given them by the law. Then, again, the idea of marital honor, as much in the higher societies as in the popular classes, the idea of honor of the young girl, even, in the popular classes, was less developed at that epoch than in ours. This change should be considered as a progress in morals; a husband indifferent as to his dishonor is always a suspicious person and liable to profit by it rather than otherwise. Public opinion has to-day become infinitely more severe for a man whose love is not disinterested; the husband for this reason must become himself more susceptible for his conjugal honor.

The scandals of the sixteenth century, the cutting sarcasm of Molière, the memoirs of the eighteenth century, prove distinctly this indiffer-

ence which was so frequent under the old régime. We have already pointed out that young girls in the higher walks of life were extremely well protected, while in the popular classes she had little, but the notion of feminine honor must have still been quite confused. Even in the nobility it seems as if at certain epochs it became obscured. De Thou relates that in the sixteenth century, Baleins, Governor of Lectoure, stabbed an officer who had abused the former's sister, by promising her marriage, and that the King of Navarre was frightened by the audaciousness of the assassin and the enormity of his crime. Proal, in his interesting work entitled "Le Crime Passionnel," states that the jury is less frightened than was the King of Navarre at the audaciousness of those who kill from love or from jealousy. This hardly means that human life has less value in the eyes of the people of the twentieth century than those of a great nobleman of the sixteenth century, but the motive which appears so serious to us probably appeared to have no value in the sixteenth century.

The last cause which seems to give to crimes from passion the aspect of ordinary crimes in modern times is our ignorance regarding a large number of crimes committed in days gone by. It is evident that at a time when medicine was in its infancy, poison must have often been employed in this type of crime, and, on the other hand, the brawls in the street were in the older days attributed to robbers, but in reality often served to carry out private vengeance.

We have, relatively speaking, numerous examples of passionary crimes in old law. In the first place we have the tragedy committed in the seventeenth century by two men occupying high social conditions, the Abbé and the Chevalier de Ganges, who both being extremely in love with their sister-in-law, the beautiful Marquise de Ganges, whose portrait was done by Mignard, and furious at being repulsed, they concentrated their efforts to avenge themselves of her disdain. In the night they penetrated into her room, the Chevalier with his sword in hand, the Abbé carrying a pistol in one hand and in the other a glass full of poison, and they forced their victim to poison herself. After she had drank the liquid the assassins waited a few minutes in order to allow the poison the time to produce its effect and to prevent any help being brought their victim. These two assassins, who belonged to the highest society, were condemned to be torn to pieces alive. Under the reign of Louis XIV came the famous Brinvilliers case. The fair assassin not only gave poison to obtain successions, but in order to break off marriages and prepare others. Beside the "*poudres de succession*," there were love powders as well, and it is well known how many and terrible were the revelations made in the ardent chamber. Louis XIV, on account of the scandal to which he would be subjected, was obliged to stop the procedure. Madame de Montespan, more especially, was shown to have asked Voisin for a powder to kill Mlle. de la Vallière, and later another in order to kill the King himself, who had abandoned her, as well as Mlle. de Fontanges, who had become the favorite in her place. She died at the age of twenty-two years, persuaded that she had been poisoned. We only know of these prominent examples, but without doubt there were a large number of crimes committed which have not been recorded, and a great many were in all probability attributed to other motives. They were probably tried as ordinary murders in spite of the opinion of very advanced minds of the epoch, and notably the great lawyer Jousse, who considered love as an excuse and the accomplice of insanity or drunkenness.

Clinical Department.

A CASE OF INTESTINAL TUBERCULOSIS WITH PSYCHONEUROTIC SYMPTOMS.

BY ARTHUR K. STONE, M.D., BOSTON.

THE patient was a young man of twenty-three years of age and a clerk. He had a phthisical family history, but had been separated from his parents from early childhood. His habits were good as regarding the use of stimulants, and he took a fair amount of exercise, belonging to a local military company. From time to time he had to be warned by me that he could not take part too freely in the social side of the organization and do his work at the store. But he had never had any serious sickness. One January he presented himself for examination, complaining that for a period of several months there had been a loss of appetite and a loss of weight. This had been accompanied by a little cough, but without expectoration. The urine showed nothing abnormal. The heart was slow, but not strong. The temperature was 98.8°. At the right apex of the lung there was slight dullness with increased fremitus, spoken and tactile; the respiration was harsh and the expiration was prolonged. During the past two weeks there had been indigestion, but the bowels were in every way regular.

Further questioning elicited the information that he was engaged and expected to be married in the near future. He had purchased a house on a mortgage; later, in attempting to pay for it, had purchased stocks on a margin and had had his margin wiped out. Consequently he was much worried and had had considerable difficulty in carrying his mortgage. On general advice he improved rapidly and his cough disappeared. In March he complained of more indigestion, which increased steadily as the time of his wedding approached. No particular kind of food appeared to bring on distress, but almost everything digested with difficulty until he had his "bachelor dinner," which he ate and drank with relish, and was married the following day and thereafter took his meals without distress, so that early in October he told me that he considered himself perfectly well. On his return after his wedding he, with other of his fellow clerks, bought out the business and started for themselves. The organization and financiering of the business fell principally on my patient's shoulders, and he worked very hard all through the summer and fall, and soon after the first of October began to have occasional attacks of indigestion, not sufficient in importance, however, to lead him to consult me. Immediately after his Thanksgiving dinner, however, he vomited and had chills during the night. About a week later he had an attack of abdominal pain, which was relieved promptly by an

injection. After that, except for cold hands and feet, he did well till Christmas time, when again he had an upset. In January he reported that he had had much pain after eating, coming in severe attacks; that not even liquids were retained, until finally some large fecal masses were passed, after which he would recover slowly. He shortly after went for a trip to Old Point Comfort and during the time there ate freely and without distress. On his return he ate an enormous meal just before leaving the steamer and his unpleasant symptoms returned at once. These attacks of pain, while quite severe at the time, were often very quickly relieved with the administration of a high enema or of hot water with 10 to 15 gr. of bromide added.

Another trouble now appeared, large and loose movements of the bowels with much gas and colic. These movements came usually at about 4 to 5 o'clock each morning and were very annoying, as they disturbed his sleep. The stomach examination gave normal amounts of acid and well digested contents. Seen in consultation with Dr. Hewes, it was agreed that the intestinal indigestion was of nervous origin. The examination of the stools failed to disclose any bacilli of tuberculosis. There was a remission in April, when for several weeks the patient attended to his business, with very little discomfort. Then the pain and diarrhea returned. The patient became emaciated, and irritable at times, turning to his business whenever he had a few days' let-up. Variations in diet appeared to have no apparent effect upon his pain or diarrhea. One day at my office, in an attack of pain, his agony was so great that opisthotonos was brought on, and this weak man balanced himself on his head and heels for some minutes. The pain, however, quickly yielded to a small subcutaneous injection of morphia, given then for the first time. Immediately after this he went to the Baptist Hospital, where he could be out of doors a great part of the time and under good nursing supervision. While there he improved during the first few days and was fairly free from pain. He was seen by one of my colleagues who, after going over the case and considering the question of tuberculosis carefully, expressed the opinion that in spite of his appearance he would consider the case a neurosis unless there was a positive diagnosis to the contrary. That same day the fecal examination enabled me to make a positive diagnosis of intestinal tuberculosis, large numbers of bacilli of tuberculosis being found in the stool.

In the hope that there might be a localization of the processes in the intestine which gave rise to the obstructive symptoms, which at no time could be located at any particular part of the abdomen, at my request Dr. G. W. W. Brewster made an exploratory laparotomy. The first coil of small intestine seen presented evidences of a well marked ulcer and as coil after coil was rapidly lifted, it was evident that the whole small intestine was thickly studded with large tubercular ulcers, and in many places the presence of lymph on the peritoneal surface of the ulcer showed how deep was the ulceration. Just above the cecum there was a thickened mass, where the lumen of the intestine was evidently contracted. This, so far as the hasty examination went, was the oldest lesion and the probable cause of the colic pains, although never had the pains been localized or had there been any tenderness pointing to any particular part of the belly. The wound was immediately closed. The patient died about a week later, a little over a year and a half from the time of the first symptoms.

The case is reported as illustrating the difficulties which may be encountered in deciding between a neurosis and a very extensive pathological process. There was every reason for mental worry and nervous instability. There was the long remission after his marriage, with the return of symptoms after a hard summer's work in financing his new business venture, and the less complete remissions on his vacation and again in March. The irregularity of the attacks of pain, the absence of localizing symptoms, all tended to make the case obscure.

Medical Progress.

PROGRESS IN DERMATOLOGY.

BY JOHN T. BOWEN, M.D., AND HARVEY P. TOWLE, M.D., BOSTON.

LIQUID AIR IN DERMATOLOGY.

THE utilization of liquid air in the field of therapeutics offers another example of the adaptation of a discovery made in one branch of science to the purposes of an entirely different branch. The commercial possibilities of liquid air were fully discussed at the time of its discovery but its use as a remedial agent was not thought of. Recently, however, it has been used with striking results in the treatment of a number of cutaneous affections. The advantages claimed for the method are that it is clean and dry, easy of application and that it produces uniform results with a smooth, thin, pliable, scarcely perceptible scar. The expense, the difficulty of keeping the substance and of obtaining a regular supply are disadvantages so great as to have limited the method to a few localities and to a small number of cases.

Trimble describes the properties of liquid air as follows: "Liquid air is the common air we breathe, very much reduced in temperature. It liquefies at 312° F. below zero. The gases that make up the normal air are practically in the same proportion when the air is liquefied. To the eye the liquid seems to be boiling, giving off fumes similar to those of nitric acid. It is slightly opalescent in color and to the touch feels cold and dry, giving a sensation of tingling. It evaporates rapidly, consequently it can be kept but a short time. We have been unable to keep it at the hospital more than two or three days. Its method of transportation is really a great obstacle as it will explode if corked tightly; therefore a small hole is always left in the stopper from which evaporation goes on." At the present time the liquid air is generally kept in a Dewar bulb which is made up of a larger outside bulb inside which is a smaller bulb. To prevent radiation as much as possible the sides of the bulbs are silvered and the air is pumped from the space between the two bulbs until a vacuum is created.

In the use of liquid air advantage is taken of its property of immediately freezing the tissues with which it comes in contact. Whitehouse says of its effects, that "a drop on the sound skin causes a sensation of burning and tingling and, if allowed to remain a moment or two, will cause a blister. In the absence of moisture no slough nor death of tissue takes place, but on a per-

spiring skin contact immediately ensues and a blister is quickly formed; on a denuded or moist surface a slough with loss of tissue follows. A mild and short exposure to the normal skin by means of the spray produces blanching followed by a moderate congestion; a longer exposure thoroughly freezes and anesthetizes the part but, if not distally situated as the ears, toes, fingers, etc., the circulation is slowly restored without affecting its integrity. It is surprising to see how deeply a part may be frozen without ultimately causing any injurious effects.

"In applications with the swab the resulting inflammatory swelling varies in degree with the amount used, the pressure employed and the location and character of the tissues. If these are firm and well nourished it is often very considerable; while if ill nourished or in a senile condition, irrespective of the age of the subject, a large dose will cause little or no reaction."

From the results of various experiments it would seem that liquid air does not destroy bacteria but that it does temporarily inhibit their activity. The results obtained from its use must, therefore, be referred to its action upon the tissues themselves rather than to its bactericidal properties. The application of liquid air with light pressure produces a temporary contraction of the capillaries with anemia, which is succeeded by a dilatation of the vessels with hyperemia and the outpouring of serum, but without destruction of tissue. A prolonged application with hard pressure causes an intense inflammatory reaction and even an obliterating endarteritis and sloughing of the part. It is apparently by reason of these changes that the results recorded are obtained. It is also stated that diseased cells are more quickly and more profoundly influenced which, it will be seen, is analogous to the action of the x-rays. White's explanation of its beneficial action in diseases of bacterial origin is that "the temporary suspension of the vitality of the germs due to the application of the liquid air gives nature an opportunity to completely destroy them, gives the system a chance to manufacture its antitoxin."

Opinions differ as to the amount of pain caused by the applications. Some writers maintain that there is usually but little pain, whereas others state that it is considerable. It seems probable, therefore, that the presence or absence of pain may be dependent upon several factors, such as the age of the patient, the condition of the tissues, the pressure employed and the duration of the application.

All writers are agreed upon the great importance of the technic. Success or failure depends upon the accuracy of the operator in applying the liquid air to the surface, his skill in applying just the pressure which will accomplish his object without causing unnecessary reaction or damage, and his judgment as to the duration of the application, the proper saturation of the swab and how frequently the treatment should be repeated. Liquid air may be applied either by spray or swab. The latter is usually preferred as it can be better controlled. A swab is made of a pine stick long enough to reach to the bottom of the bulb by wrapping absorbent cotton about one end. The cotton is moulded to fit the surface of the lesion to be treated, making it flat or round or oval as the case may demand. The swab is dipped into the liquid air until saturated after which the surplus liquid is allowed to drip off. It is then applied accurately to the surface of the lesion with light, medium or hard pressure, according to the intensity of the effect which is desired. The ability to always use the same pressure seems to be the most difficult part of the technic to acquire. Trimble's description of what is meant by light, medium and hard pressure is, therefore, helpful. He compares "light pressure" to the light touch with which the Paquelin cautery is used in lumbago to produce a slight erythema. "'Medium pressure' is used when the applicator is held upon the lesion with sufficient firmness to prevent its slipping from its place and hard enough to depress the skin slightly." Another point made is the removal of all crusts before making the application. It is also advisable that all moist or denuded surfaces should be covered with a thin layer of gauze in order to prevent the swab from freezing fast to the surface.

In regard to the amount of pressure to be used in the treatment of the various conditions, light pressure of short duration is employed in such affections as lupus, erythematosus and port-wine marks; medium pressure in pigmented and hairy nevi, angiomata, lymphangioma and lupus vulgaris; and firm pressure of considerable duration — twenty to sixty seconds — in the scattered nodules of lupus vulgaris and in epithelioma. Whitehouse advises that in the treatment of epithelioma and rodent ulcer the pressure should be exerted upon the periphery of the lesion rather than upon the center in order to prevent recurrence. He also uses liquid air as a diagnostic aid in distinguishing the pearly cicatricial nodules, occasionally seen on the periphery of a healed lesion, from true epitheliomatous nodules, relying upon the fact that the diseased tissue is frozen while the scar tissue is not appreciably affected.

The time when the application should be repeated demands the exercise of considerable judgment, for if the treatment is given too frequently it intensifies the reaction and causes unnecessary destruction of tissue. It is agreed that the best results are obtained when the operator proceeds slowly. Therefore, it has become the rule to wait until the effects of the first application have entirely passed off before making the second. Some, indeed, wait until the crust resulting from the preceding application has fallen before giving another treatment. It is claimed that if the operator is skillful, superficial affections may be removed with practically no scarring, and deeper affections with a scar which is so thin and pliable as to be scarcely noticeable. It is said that it is only when the applications are too long continued and the pressure too hard that tough, irregular scars result.

A brief résumé of some of the cases reported will give the best idea of the character of the cases in which liquid air is used, the method employed and the results obtained. For example, Trimble reports eight cases of hairy, pigmented nevi. Case I was a boy, aged eleven, with a brown, very hairy, pigmented lesion one and a half inches long and one-half inch wide, situated upon the upper eyelid. After four applications the hair began to disappear, ulceration commenced and a crust formed. Healing took place beneath the crust leaving a practically normal skin. Case II, a girl, aged five, presented on the cheek near the angle of the mouth a deeply pigmented, hairy lesion of the size of a twenty-five-cent piece. Six applications were made, the last causing some inflammation. The result was good, only slight scarring resulting. Case III, girl, aged sixteen; nevus of mouse-skin variety on side of nose, three fourths of an inch long and one-half inch wide, covered with long hair. After seven applications there remained only a healthy scar with slight pigmentation at one point. Case IV, girl, aged six; pigmented lesion on right temple. Three applications resulted in a smooth white scar which was scarcely noticeable. Case V, woman, aged twenty-four; lesion on left lower cheek, pigmented and covered with thick, reddish-brown hairs; size of a twenty-five-cent piece. Five applications removed the lesion with the exception of one small spot in the center. Case VI, boy, aged seventeen; dark brown nevus on cheek, size of twenty-five-cent piece; covered with coarse brown hair. Six applications cured with very mild scarring. Case VII, girl, aged twenty; nevus about the size of a five-cent piece, under the chin; black and covered with coarse black hairs. Entirely removed by seven applications except for one patch the size of the head of a match and with practically no scarring. Case VIII, girl, aged twenty; mouse-skin nevus, size of ten-cent piece, on the shin; central portion verrucous and projecting one-eighth inch above the surface. Four applications cured without remaining pigmentation and without a noticeable scar. All of these cases remained under observation for over a year and none showed any sign of recurrence.

Whitehouse reports three cases of pigmented nevi and two cases of hairy nevi in which his results were similar to those of Trimble. In addition he reports cases of vascular nevi, lupus erythematosus, lupus vulgaris and fifteen cases of epithelioma. As a result of a single application, a *vascular nevus*, the size of the finger nail, situated on the nose, disappeared completely within three weeks, leaving a smooth flat scar. Three months later there was no sign of a return. A port-wine mark on the nose, twice the size of the last, disappeared within three months after eight light-pressure applications, leaving a very superficial, atrophic-looking scar. No return. An irregular vascular nevus over the angle of the jaw and the adjacent part of the neck was removed by six applications and showed no signs of return after two years. In a case of *lupus erythematosus* of three years' duration, one patch on the cheek the size of the thumb nail was cured by three applications and another, slightly larger, indurated patch on the nose by five or six applications with smooth, superficial scars. In a second case a patch of one and a half years' duration, situated on the temple, had been almost completely removed by six applications with moderate pressure, when the patient disappeared. A patch of *lupus vulgaris*, nearly one inch in diameter, of three years' duration, was completely cured by one fairly severe, one moderately severe and two milder applications, leaving a smooth, pliable, but slightly depressed scar. No tendency to recurrence shown two years later. In another case of lupus vulgaris five isolated tubercles remained of a patch which had been previously treated by other measures. Deep boring with a pointed applicator destroyed the tubercles but produced a marked reaction. Sixteen months later there was a questionable recurrence of one tubercle which one application would cure. The fifteen cases of *epithelioma* were of the type commonly seen about the head and face and unaccompanied by glandular involvement. The following will serve as examples. An epithelioma, one quarter of an inch in size, was cured by a single application with firm pressure and showed no recurrence a year and a half later. Two other cases of the same size were also removed by one application. Thirteen months later one showed two pin-head recurrent nodules which were attributed to a tag left attached at the time of the first application. The second showed no return. Several other cases, varying in size from one quarter to three quarters of an inch, were cured by from one to four applications and showed no return in from two to three and a half years. An excavation involving almost the whole width of the lip and extending into the mouth was left by the removal of a fungating growth by Marsden's paste. Nine severe applications of liquid air were then made to the mucous surface. A group of nodules developed on the chin at a distance from the original growth. Two applications were made to the nodules and two to the original growth, making eleven in all. Three months from the first application the whole had healed perfectly with a scar level with the surface. The lip was slightly shortened but the contour was not affected.

The above cases are sufficient, without detailing similar cases reported by other men, to show the striking results obtained by the use of liquid air. Certainly they are not equalled by any other method with the possible exception of excision. Unfortunately the general use of liquid air is impossible because of the very great difficulty of obtaining it. Its employment at present is almost confined to New York, and even there it is sometimes difficult to secure a regular supply. It is to be hoped that some method will be invented which will render its production commercially profitable and thereby bring it within the reach of the profession generally.

TENTH ANNUAL MEETING, HELD AT ATLANTIC CITY, N. J., JUNE 3 AND 4, 1907.

(Concluded from No. 16, p. 535.)

GASTRIC DISTURBANCES CAUSED BY HERNIA.

DR. MAX BALLIN, of Detroit, Mich., read this paper. He stated that any and every kind of hernia caused more or less gastric or intestinal trouble. The common large inguinal herniæ, if reducible, were responsible for flatulence, constipation, pain in the back and groins; if adherent, all these symptoms became more pronounced. Omental adhesions in a hernial sac could make a patient so miserable by loss of appetite and indigestion that serious loss of weight resulted, and there were cases of supposed malignant disease, where afterwards radical operation of the hernia removed all the intestinal disorders. It should be borne in mind that if in a hernia any adhesions existed between the hernial sac and its contents, a truss would usually aggravate all the symptoms by pressure on the unreduced parts. Generally speaking, in adherent hernia, a truss was contra-indicated. Wherever located, post-operative ruptures were most troublesome to the patient, but Dr. Ballin said that the main object of his paper was to call attention to intestinal disorders caused by small herniæ that were not easily discovered. Of these he considered in detail four kinds, namely: 1. The so-called incomplete inguinal hernia; (2) the small femoral hernia; (3) umbilical hernia; (4) epigastric hernia, in or lateral to the linea alba, and peritoneal lipoma. Under the latter heading he included hernia protruding in or close to the linea alba, between the xiphoid process and the umbilicus. These herniæ occurred very rarely below the umbilicus, and were apparently due to congenital or acquired defects in the linea alba, although some claimed that loss of fat was an important factor in their etiology. Others claimed that just the opposite, adiposity, predisposed to such weakness, the fat replacing to some extent the resistant fibrous tissue. Epigastric hernia and lipoma might exist for many years without causing any symptoms. Then, suddenly, symptoms might arise, the chief one being pain. Usually, these epigastric herniæ, on account of their size and the peculiar lipoma formation and adhesions, were not benefited by trusses and bandages, and a surgical operation was indicated. In conclusion, Dr. Ballin said that many cases of obscure abdominal trouble, colics and vomiting, could be caused by hernia, and that it was very important to look in all such cases for small ruptures. These could be of any of the known varieties, but of special importance in producing gastric symptoms were the small epigastric herniæ and the peritoneal lipomas.

DR. MAX EINHORN, of New York City, said that, according to his experience, these herniæ, especially those of the epigastric variety, were very frequent indeed. He probably saw three or four every week, and he did not think that one half or even one third gave rise to any symptoms. In the majority of these cases he ignored the hernia entirely, and considered it a mistake, sometimes, even to call the patient's attention to its existence.

DR. J. A. LICHTY, of Pittsburg, said he had seen only two cases of epigastric hernia, and in those two instances the patients did not complain of any symptoms referable to the hernia.

DR. J. C. JOHNSON, of Atlanta, said that in a case of epigastric hernia which he saw recently the chief symptom was periodical attacks of pain. This was the only case of epigastric hernia he could recall among several thousand examinations.

DR. G. W. MCCASKEY, of Fort Wayne, said he was greatly astonished at the frequency with which Dr. Einhorn met with cases of epigastric hernia.

DR. A. L. BENEDICT said the statements made by the various speakers in regard to the frequency and infrequency of epigastric hernia showed either the personal equation or a peculiar coincidence. Personally, he saw these cases rather frequently, perhaps one every week or two; some of them good-sized epigastric herniæ; others so small that they could scarcely be called herniæ, but rather epigastric finger-points. He had never seen a single case in which the symptoms could be attributed to the hernia itself.

DR. I. ADLER, of New York City, said he wished to protest against the statement that epigastric herniæ were so very frequent. The stomach symptoms in these cases were not necessarily due to the presence of the hernia. Occasionally, however, an operation on such a hernia would act as a suggestive measure and relieve the symptoms, but there were still other cases where he agreed with Dr. Ballin that an operation was necessary, particularly in those cases where there were inflammatory adhesions.

DR. S. J. MELTZER said it was not only incomplete herniæ that were liable to give trouble, as the simple pressure of the intestines against a patulous internal ring or against some diastasis in the abdominal muscle was not infrequently the cause of such pains, which were always relieved by the application of a well-fitting truss. Doubtless, there were some cases of incomplete herniæ which were not relieved by trusses; but even if a truss was effective, why should a man wear a truss for thirty years or more when he could be radically cured in less than a fortnight?

DR. CHARLES D. AARON, of Detroit, said a case of epigastric hernia which he reported ten years ago was that of a man who had been an invalid practically for fifteen years, because of an epigastric hernia about the size of a marble, with an opening into the linea alba scarcely larger than the point of a pencil. He was completely relieved by an operation. These cases were not the kind where the opening was large enough to admit even the finger-tip, and replacement was impossible.

DR. J. KAUFMANN, of New York City, thought there were cases of epigastric hernia which gave rise to serious trouble and which could not be cured by putting the patients to bed. In any case that was giving rise to symptoms, he would certainly advise an operation.

The discussion was continued by DRS. J. FUHS, of Brookline, G. W. MCCASKEY, of Fort Wayne, and was then closed by DR. BALLIN.

THE GASES OF THE INTESTINE, WITH DEMONSTRATION OF AN ORIGINAL APPARATUS FOR THE COLLECTION AND ANALYSIS OF STOMACH AND INTESTINAL GASES.

By DR. S. BASCH, of New York. The author stated that the study of the intestinal gases possessed interest mainly as a physiological and chemical problem, but the important rôle which they played in a number of

abnormal conditions clothed them, clinically, with more than theoretical interest. As was well known, the intestinal tract, after the very first ingestion of food, was never entirely free from gases. Throughout life there was a constant cycle of production and elimination. Under healthy conditions this balance of interchange proceeded without discomfort or marked disturbance, but if from any cause there was a derangement of its equilibrium, then flatulence, borborygmi, meteorism, tympanites and other conditions, varying in their significance from the merest discomfort to the severest gravity, might result. It was formerly held that the greater portion of the intestinal gases passed off per anum. This view was now known to have been erroneous, and it was conceded that in the healthy individual at least as much disappeared through absorption into the blood and expulsion by the respiratory tract.

Under a mixed diet the prevailing gas formed in the intestine was CO_2. The amount, naturally, was larger under a heavy than under a light form of diet. CO_2, being a product of fermentation, was most abundantly evolved in the earlier stages of both intestinal and fecal fermentation, while the hydrocarbon series, being the result of putrefactive decomposition, developed, in general, later. H_2S also increased as the fermentative changes were replaced by the putrefactive. It could not be quantitatively determined in these gas mixtures, but its presence was demonstrated by exposing strips of filter paper soaked with lead acetate solution to the gas.

Dr. S. J. Meltzer, of New York City, said that, in view of the present tendency to ascribe a lot of trouble to the faulty digestion of proteids, it would be interesting to learn in what proportion the intestinal gases varied when the patient was on a proteid or carbohydrate diet.

Dr. S. Basch, of New York City, in closing, said it had been shown that the carbohydrates were largely responsible for the production of carbonic acid gas, while the proteids were responsible for the production of marsh gas, ammonia and putrefactive gases.

LACK OF GASTRIC MUCUS AND ITS RELATION TO HYPERACIDITY AND TO GASTRIC ULCER.

Dr. J. Kaufmann, of New York, read this paper, in which he emphasized the fact that a lack of gastric mucus should be considered an unfavorable symptom, and that a diminished secretion of mucus and insufficient mucous covering deprived the gastric mucosa of its protection against all harmfuli nfluences and particularly against the digestive activity of its own secretion. The routine examinations of stomach contents had heretofore been principally directed toward the study of the gastric juice and its disturbed secretion. A more careful study of the protective secretion of mucus and its disturbances should be systematically made. We were all familiar with the increase of mucus in certain gastric conditions, but too little attention had been paid so far to the decrease and the lack of secretion of gastric mucus. Dr. Kaufmann said his observations during recent years had convinced him that decrease and lack of secretion of gastric mucus was of frequent occurrence and played an important rôle in the pathology of diseases of the stomach.

Dr. Max Einhorn, of New York City, said he did not agree with Dr. Kaufmann that the symptoms of hyperchlorhydria in achylia gastrica could be explained by this condition of a lack of mucus. The number of cases in which there was an absence of mucus was very large, while the number that complained of symptoms of hyperchlorhydria was very small. There was also another variety of gastric disorder, in which there was a great deal of gastric juice and also mucus, and he could recall a number of cases where the mucus composed fully one half of the gastric filtrate.

Dr. Kaufmann, in closing, said that in his paper he limited himself to cases in which there was a lack of secretion of gastric mucus. An increase of mucus was a subject that he did not discuss at all. A lack of secretion of gastric mucus certainly played an important rôle in the pathology of the stomach, and was deserving of more consideration than it had received thus far.

DEMONSTRATION OF ESTIMATING PERCENTAGE OF PROTEIDS, FATS AND CARBOHYDRATES IN FOOD.

By Prof. Irving Fisher, of New Haven. In connection with this demonstration the speaker stated that there had been previously two methods in use for estimating the proteids, fats and carbohydrates in foods, which might be distinguished as the method of weight per cent and the method of calories per ounce. By the first method the weight of each food is multiplied by the percentage of weight of proteid, fat or carbohydrate which it contains. The products give the weights of the three elements. The total calories were then found by multiplying these weights by the food value of proteids, fats and carbohydrates per gram and adding the results. This method was too laborious to be of much practical service to physicians. In the second method, a table was prepared, expressing in calories the proteids, fats and carbohydrates in an ounce of each given food. This method had the advantage that the proteids, fats and carbohydrates and total fuel value were all measured in the same units, namely, calories. A simpler method than either of the preceding was to form a table giving the per cent of total calories in the form of proteid, fat and carbohydrate. This method had the advantage of being easily visualized by graphic representation, and of lending itself to quick computation, by means of a mechanical diet indicator.

Dr. A. L. Benedict, of Buffalo, said Professor Fisher's demonstration had given a very clear illustration of what small quantities of food the average adult really required, and how much we ate in excess of that amount. To verify that fact, one had only to observe the average diner at his hotel table, where even in the bread and butter that he munched before his meal, and the olives he consumed between the courses, and the fruit and nuts and ice cream he took for dessert, he had eaten more than his daily ration of calories.

STUDY OF URINARY ACIDITY.

Dr. A. L. Benedict, of Buffalo, read a paper on this subject, in which he reported in detail his clinical deductions from a study of the urinary acidity. He was unable to verify the observation that there was an alkaline and an acid tide in the urine in the course of digestion, nor was he able to verify the observation in patients that rheumatism was associated with superacidity. In acute articular rheumatism, the acidity was not as high as we should expect. In numerous observations of the urine he had rarely found it alkaline, nor had he found the decrease in acid units after meals, as we should expect.

AN UNUSUAL CASE OF ULCER OF THE STOMACH.

By Drs. J. M. T. Finney and J. Friedenwald, of Baltimore. In this case the clinical diagnosis of gastric ulcer was made, which was confirmed by the gross findings in the laboratory and subsequently by the microscope. At the operation, a markedly indurated ulcer of the stomach was found, with enlarged glands in the mesentery. The case was thereupon

regarded as one of cancer, and a gastrectomy was done, with the removal of a large portion of the stomach. The case was interesting from the fact that notwithstanding the existence of a markedly indurated ulcer in the stomach, the symptoms which were presented were by no means distinctive of that condition, and even upon direct inspection it could not be differentiated from carcinoma. The speaker emphasized the fact that all indurated ulcerations of doubtful character situated in the stomach should be regarded as carcinomatous, inasmuch as it is impossible in many of these cases to differentiate ulcers from carcinoma by simple inspection; and again, because in a certain number of these cases a carcinoma was apt to develop upon the indurated border of an old ulcer.

DR. J. A. LICHTY, of Pittsburg, said the case reported in this paper was very interesting on account of the fact that some enlarged glands were found in the mesentery. While he was aware of the fact that surgeons were inclined to consider these small enlarged glands in the mesentery as almost positive proof of a malignant condition, and a positive indication for a radical operation, in cases which would formerly have been regarded as benign, he personally did not understand why these glandular enlargements should not be the result of an infection in the presence of a good-sized gastric ulcer, and he was not convinced that they were necessarily an indication of a malignant condition.

DR. J. KAUFMANN, of New York City, said he had seen cases of gastric ulcer which caused enlargement and hardening of glands in the mesentery, and where a gastro-enterostomy was performed and the future development of the case proved that the ulcer was of benign character.

DR. G. W. MCCASKEY, of Fort Wayne, expressed the belief that every indurated ulcer of the stomach, after an exploration, should, if possible, be freely and liberally excised. The frequency with which cancer developed from an ulcer base should not be lost sight of.

THE FACTORS CONCERNED IN THE HEALING OF PEPTIC ULCER.

DR. F. B. TURCK premised this paper upon a reassertion of his former contention, based upon experiments on a large number of animals, that true peptic ulcer had for its most important factor certain alterations in the alimentary canal, with subsequent changes in the blood, characterized by diminution of the normal protective bodies, and that these etiological factors were general in character and not local. The progressive microscopic picture revealed a process of breaking down — the cells themselves jagged and irregular in form, without round cell infiltration, and a disintegrating and diminishing connective tissue structure. When the process of repair was instituted those cells capable of rehabilitation reasserted their physiological activity; those that had been injured beyond recall were carried away by a process of leucocytosis; new material for the formation of connective tissue was introduced, which progressively drew the edges of the ulcer together, acting in constricting bands. Hence the scar that remained. Similar factors that were active in the normal defense of the tissues were also concerned in the process of reconstruction. Processes of repair were impossible without restoration of the normal defenses of the blood.

Dr. Turck's paper was discussed by DRS. S. J. MELTZER, of New York City, and J. C. HEMMETER, of Baltimore.

DEMONSTRATION OF A MODIFICATION OF THE BOAS TEST FOR BLOOD IN THE FECES.

DR. A. L. BENEDICT, of Buffalo, said that gasoline was first added to the feces to extract the fats. Then old, ozenized oil of turpentine was added, and a fresh solution of guaiac. The test was just as delicate as the ordinary Boas test, and a great deal simpler.

THE EFFECT OF DESTRUCTION OF THE SALIVARY GLANDS (BY DISEASE OR EXPERIMENT) ON THE GASTRIC SECRETION. A POSSIBLE INTERNAL SECRETION OF THE SALIVARY GLANDS.

By DR. J. C. HEMMETER, of Baltimore. The speaker stated that his attention was first attracted to this subject by the case of a woman who was suffering from septic parotitis, which involved also the submaxillary and sublingual glands. Repeated examinations of the stomach contents in this case revealed an entire absence of hydrochloric acid and enzymes, with no proteolytic and no milk-curdling effect. Subsequently, the septic parotitis improved, and this was followed in turn by a restoration of the normal gastric juice. This case, Dr. Hemmeter said, brought to his mind the two cases of salivary gland disease and known as Mikulicz's disease, which consisted of a bilateral induration of all the human salivary glands, resembling adenoma, and in which a chemical examination of the stomach contents showed this same deficit of hydrochloric acid and other gastric secretions.

Influenced by a knowledge of these cases, the speaker said he undertook a series of experiments on three dogs with experimental accessory stomachs (Pawlow). After determining the proteolytic and milk-curdling power of the amount of hydrochloric acid in the secretion from the accessory stomachs of these animals, so as to learn what their gastric juice would accomplish under normal conditions, their salivary glands were removed. It was found comparatively easy to extirpate the submaxillary and sublingual glands, but extirpation of the parotid was accomplished with great difficulty on account of the distance it extended backward underneath the skull. Still, even if a portion of the gland was left behind, its usefulness would be destroyed, providing its nerve and vascular connection was severed. It was found that extirpation of the submaxillary and sublingual glands had some deleterious effect on the gastric secretion, but after removal of the parotid the quantity of hydrochloric acid and the proteolytic power of the gastric juice gradually became less and less, until four or five days after the removal of the last portion of the salivary glands, the canine gastric juice no longer gave any evidence of hydrochloric acid, milk-coagulating or of proteolytic power, and the accessory pouch of the stomach secreted nothing but a serous liquid containing a considerable trace of mucin. Upon removal of the accessory stomach there were no evidences of inflammation, and to all appearances the cells of the peptic ducts were normal.

A second series of experiments was then undertaken. An esophageal fistula was produced upon a number of normal dogs, so that they could chew and swallow their food with apparent enjoyment. This food, however, was not permitted to enter the stomach, but was collected at the esophageal fistula and fed to other dogs who had been previously experimented on by having their salivary glands removed, with consequent loss of gastric secretion. The introduction of this food into the stomach of these animals failed to excite any secretion of gastric juice. This experiment proved that the failure of gastric secretion after extirpation of the salivary glands was not due to absence of canine saliva, nor to lack of mastication.

In order to corroborate these findings still further, the salivary glands of a number of healthy dogs that had been recently killed in the course of various experiments were obtained, and ground up with quartz,

and after a rather elaborate process a salivary extract was obtained free from proteid in the shape of a thick, opalescent, gelatinous liquid, which was injected into the superficial veins or peritoneal cavity of the dogs that had lost their power of normal gastric secretion after extirpation of their salivary glands. These injections were followed within one half to two hours by such a resumption of the secretion of hydrochloric acid and ferments that presence of gastric juice could be determined by the ordinary methods. This restoration was only temporary, however, lasting eight or ten hours, the period depending largely on the amount of the extract that was injected. It was also apparent that the injection of this salivary extract had a marked vaso-motor influence; and the speaker said that in his efforts to produce a prolonged secretion of hydrochloric acid he sometimes injected too much, producing a surprising increase of blood pressure. When fed by the mouth, the extract had no effect on the secretion of hydrochloric acid. On the other hand, when injected, it was effective even after all the nerve supply of the stomach had been cut off.

Dr. Hemmeter said he had not been able to isolate from this extract of the salivary glands the active principle, a substance like that obtained from the suprarenal gland.

The speaker also referred to some experiments upon normal human subjects who were one day given a test meal which they were permitted to chew and swallow naturally, and the following day the identical test meal was poured into the stomach through a test tube. A chemical analysis of the gastric juice after the second method of feeding showed a considerable deficit of hydrochloric acid and enzymes. He also referred to Pawlow's psychic secretion. If a hungry dog even saw a piece of meat it had the effect of exciting an immediate flow of gastric juice — the so-called psychical secretion (Pawlow), or *appetit-saft*, which was brought about by the intermediation of nerves.

Dr. S. J. Meltzer, of New York City, said if Dr. Hemmeter's experiments could be verified, a new and interesting condition confronted us. The discovery of Bayliss and Starling established the fact that the secretion of the stomach produced in the duodenum a substance which they called secretin, and which stimulated the secretion of the pancreas. Now, Dr. Hemmeter found that a secretion of the salivary glands was essential to produce a secretion from the stomach. The substance Dr. Hemmeter found in the extract of the salivary glands apparently belonged to the group which Starling designated as hormones.

The discussion was continued by Dr. F. B. Turck, of Chicago, and Dr. J. C. Johnson, of Atlanta, and was closed by Dr. Hemmeter.

GASTRIC ULCER COMPLICATED WITH THE SYMPTOMS OF CHOLELITHIASIS.

Dr. J. A. Lichty, of Pittsburg, read this paper, in which he offered the following conclusions: (1) The diagnosis of uncomplicated gastric ulcer should be made without difficulty. (2) When complications existed, it may be impossible to form an exact opinion of the pathological condition in this region of the abdominal cavity before a laparotomy is done. (3) A careful and methodical anamnesis in these cases is of the utmost importance.

Dr. J. P. Sawyer, of Cleveland, said that for a number of years he had been following up a class of cases in which the symptoms at first were those of a catarrhal gastritis, and then, in the course of a few years, if not cured, they developed an infection of the gall bladder or appendix, as shown at subsequent operation.

THERAPEUTICS OF MINERAL WATERS OF THE FRENCH LICK TYPE IN GASTRO-INTESTINAL DISORDERS.

Dr. G. D. Kahlo, of Indianapolis, read this paper, which contained his observations upon the therapeutic indications of alkaline-saline waters based upon a year's clinical experience at French Lick Springs, and the results of certain experiments made upon healthy subjects, together with a brief description of the water, and a general outline of the treatment. He had found the waters at the French Lick Springs especially valuable in gastric diseases, particularly after the abuse of alcohol, and equally favorable in hepatic disorders and hyperchlorhydria.

Dr. S. Basch, of New York City, said we had in the past made the mistake of sending too many of our patients abroad when we had so many excellent springs in our own country which compared very favorably with those in Europe. Unfortunately, at most of our springs there was a lack of proper attention to detail, not only in regard to the analysis of the waters, but also in regard to the general supervision of the springs. In Europe, the physicians who practiced at such resorts were usually trained in physiology and body metabolism, while in this country that factor was almost entirely neglected. Furthermore, the patients were not kept under proper control. The hotels were usually on the American plan, and the patient did not attempt to restrict his appetite, and often drank the waters in unreasonable amounts. He thought the association should interest itself in this important subject, and by arousing the proper interest, actual results could be obtained.

Book Reviews.

Modern Medicine, Its Theory and Practice. In Original Contributions by American and Foreign Authors. Edited by William Osler, M.D., Regius Professor of Medicine in Oxford University, England, assisted by Thomas McCrae, M.D., Associate Professor of Medicine and Clinical Therapeutics in the Johns Hopkins University, Baltimore. Vols. I and II. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1907.

This system of medicine, for such it deserves to be called, has long been awaited by medical men, both in this country and abroad. If one may judge of the succeeding volumes from the two which have already appeared, there will be no disappointment. Medical writing at the present time is at best difficult. Our knowledge of many diseases is imperfect; our therapeutic resources are in a state of uncertainty, and many departments of medicine are in a continual state of flux. The result is that a system of medicine of so pretentious a character as this edited by Dr. Osler should mark a certain epoch in the history of medical progress, representing as it does the matured opinion of special students in many correlated branches of medical science. It is, however, not to be expected that what is here set down will be forthwith accepted ten years hence, and the demand will surely come for a new and complete revision of the work as it at present stands, or of another to take its place.

The scope of this encyclopedic work on Modern Medicine is comprehensive. Dr. Osler has gathered

together men of acknowledged distinction, both in this country and in England, to contribute to the various volumes. The work concerns itself with medicine alone. The first volume, following an admirable introduction by Dr. Osler, which in happy style discusses from the historical standpoint the evolution of internal medicine, takes up the following subjects: predisposition and immunity; diseases caused by physical agents; diseases caused by chemical agents; diseases caused by organic agents; diseases due to vegetable parasites other than bacteria; diseases caused by protozoa; diseases caused by animal parasites; nutrition and constitutional diseases. Under these main headings twenty-two men write, including such names as Adami, Calkins, Chittenden, Howard, Noguchi, Novy, Stiles and Wright. The articles are, without exception, written with care and with a just sense of personal responsibility, which is not always in evidence in composite writings of this sort. A particularly significant article is that by Adami on inheritance and disease. Wright, of Boston, contributes the article on actinomycosis and allied parasites. The protozoa are discussed by Calkins; questions of nutrition by Chittenden and Mendel, and constitutional diseases by Futcher, Anders and others. It would be invidious to draw particular attention to any one of these admirable summaries of existing knowledge. The volume is liberally, although not profusely, illustrated, and evidently no care has been spared to render the series attractive from the standpoint of the bookmaker's art as well as from the character of the contributions. The second volume, which has appeared within a short time, is concerned with the infectious diseases and numbers eighteen contributors, among whom are James Carroll, Councilman, Hektoen, McCollom, Pearce and Shiga. A melancholy interest will attach to Carroll's article on yellow fever since within a few weeks the news has come of his death, probably superinduced by the voluntary attack of the disease which he incurred during the investigation of the mosquito theory. This volume likewise contains a most admirable series of articles by men whose statements must be regarded with respect. Smallpox by Councilman, influenza by Lord, and typhoid fever by McCrae are among the most significant contributions to this volume. In Councilman's paper on smallpox it is regrettable that the publishers have not seen fit to reproduce on adequate paper the high magnifications of the smallpox parasite. Photographs of the gross appearances of the smallpox eruption are printed on special paper, although almost as satisfactory a result would have been obtained had they been printed in the text, whereas, microscopic sections which absolutely demanded special paper are printed in the text. We refer particularly to the cuts on pages 256 and 258. These cuts are certainly to be regarded as among the most important, not only in this but in any of the volumes, and no pains should have been spared to bring them out in the clearest possible form.

The succeeding volumes, five in number, are promised at short intervals, which is exceedingly desirable in a work of this sort. We shall await their appearance with interest, and we have no question that they will completely fulfil the promise of their predecessors. The book is sure of a wide and sympathetic reading on the part of those desirous of keeping up with the advances in modern medicine, whose time does not permit of recourse to original sources.

A Treatise on the Principles and Practice of Medicine. By ARTHUR R. EDWARDS, M.D., Professor of the Principles and Practice of Medicine and of Clinical Medicine in the Northwestern University Medical School, Chicago. Illustrated. Pp. 1328. Philadelphia and New York: Lea Brothers & Co. 1907.

It is, perhaps, a little venturesome for an author, however wide his experience may be, to write another textbook on the Principles and Practice of Medicine. The multiplicity of treatises of this sort has, however, not deterred Dr. Edwards from adding another book to the list. In writing the book he has had the definite idea in view of giving prominence to facts rather than to theories, and of studying the conditions of disease as they appear at the bedside rather than in the typical form as so often described in textbooks. While recognizing fully that the science of medicine so far as developed should be adequately discussed, the author urges as the final object of a book of this sort the application of knowledge to the cure or alleviation of disease. Hence, more than usual space has been given to treatment, together with the physiological action of drugs.

The book is divided into twelve sections, dealing respectively with the following subjects: specific infections; diseases of the circulation; diseases of the respiratory tract; diseases of the digestive tract; diseases of the kidney; diseases of the blood; diseases of the ductless glands; constitutional diseases; diseases of the nervous system; intoxication; sunstroke; and diseases due to animal parasites. From this it is seen that the scope of the book is comprehensive, and of necessity many of the subjects are treated in somewhat cursory fashion. The discussion of each disease follows the time-honored arrangement of definition, etiology, symptoms, diagnosis, prognosis and treatment. Authors are frequently quoted in the text, but without reference to their special contributions. We are sorry in this as in other general textbooks of medicine to find in the treatment of diseases of the nervous system no adequate diagnostic aids in the way of a brief statement of the essential anatomical points, particularly in relation to diseases of the spinal cord. Certain diagrams are given, such as appear in the ordinary textbook, but this is not enough to make clear the symptomatology of the diseases which follow. The nervous system in general is rapidly outgrowing the scope of a textbook on general internal medicine.

The book is well illustrated, though not profusely, and without question will find a place of usefulness.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, OCTOBER 24, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 Boylston Street, Boston, Mass.

PHARMACISTS AND PHYSICIANS.

We reproduce with pleasure and we believe with profit to our readers the extract which follows, from an address delivered by Dr. Solomon Solis-Cohen, of Philadelphia, former chairman of the Section on Pharmacology and Therapeutics of the American Medical Association, before the meeting of the American Pharmaceutical Association. These statements are more temperate in tone and more just in appreciation than many which were being made a year or two ago. They are in great measure in accord with our own views as set forth in an editorial published in the Journal, March 1, 1906, and which we have seen no reason to alter.

There is no longer the demand that physicians should not go outside of the pharmacopeia in their prescribing, and in other ways the pendulum, having swung too far in both directions, seems to be reaching a state of oscillatory equilibrium. The manufacturing pharmacist and the dispensing pharmacist are both doing more careful and more useful work than ever before, and increasingly merit in their best representatives the confidence and co-operation of the physician.

Dr. Solis-Cohen spoke as follows:

"For the last few years pharmacists and physicians, working side by side, have set themselves to amend some of their errors and mistakes of the past. It lies not in the mouth of the physician to reproach the pharmacist, nor in the mouth of the pharmacist to reproach the physician. We have erred together, and we are determined to redeem ourselves together. The mere trade in patent medicines, the frauds and fakes and deceits of all kinds, need not here concern us. These are crimes, not errors. There are many other crimes outside of the domain of medicine and outside of the domain of pharmacy, and we have not engaged in a general reformatory enterprise. Other organizations and other agencies exist for such purposes, and in their work some of us, as individuals, are taking more or less active part. But the movement to make the drugs, whether the products of manufacturing houses or the products of individual pharmacists, which are dispensed over the counter upon prescription, — the movement to make these drugs in fact what in name they purport to be, is one in which the organized professions of medicine and pharmacy have a common and lively interest, and in which the physician's patients, the druggist's customers, have the greatest interest of all. I recognize and you recognize — we must recognize — that in the general progress of science, the general advance of discovery, the general improvement of the arts, there must be corresponding progress, discovery, improvement, in the processes of manufacture and preparation of pharmaceuticals. Hence there is abundant room, and, indeed, necessity for the enterprise of chemical and pharmacal manufacturers, whether they occupy the general field of pharmaceutic production or devote themselves to specialties. For example, how can the individual pharmacist undertake to prepare and supply the great group of animal extracts and serums which play such a large part in the therapeutics of to-day? And so with various inorganic chemical compounds, alkaloids and even some galenicals. The retail pharmacist should be skilled and enterprising, but there are many things in modern pharmacy for which the average pharmacist, with his necessarily limited time, space and equipment, must look to some establishment which possesses the proper facilities and is thoroughly organized to do well on a large scale what can only be done imperfectly on a small scale. We all recognize that, and the American Medical Association has taken steps, individual physicians have taken steps, to place the medical profession in proper relation with the great manufacturing houses, both those of just fame in Europe and those which are in so high degree a credit to progressive American pharmacy and to American business enterprise. We want to have the most friendly relations with them all, so that these firms may be encouraged to prepare and to offer to us, for the benefit of our patients, the best and purest and most definite pharmaceutical products. And yet, after all is said on this side of the question, there is still a place, and there must always be a place, honorable and important, for the individual pharmacist, for the retail druggist, — call him by whatever name you please, — for the individual who studies and practices as a scientific art the profession of pharmacy. . . . And now just a word as to the outlook for the future of pharmacy.

"The dependence of the patient upon the physician is reflected in the dependence of the physician upon the pharmacist. It is true that the greatest advances which have been made in medicine are

those of preventive medicine, of hygiene and sanitation. We are aiming to teach people how to live sanely and avoid disease. We aim to teach communities to purify their water, and keep their streets clean, and incinerate their garbage, and isolate those sick of contagious disease, and safeguard their food supplies, and do all other things necessary to provide a wholesome environment for the mass and for the individual. It is also true that when disease occurs we now make increased use of those measures which I have ventured to term 'Physiologic Therapeutics,' that is, methods other than drug giving, air and light, and food and water, and rest and exercise, and immunizing sera and antitoxins and radiant forces and mental influence; in a word, those influences which have been potent in the evolution of man and are most potent in restoring him to his normal condition. Yet beyond the present domain of preventive medicine, and beyond the present domain of physical and mental therapeutics, is a great domain of disease in which alleviation and remedy can be best achieved through those means, which you, members of the American Pharmaceutical Association, prepare and furnish to the physician.

"It is a poor boast to say that one knows only four, or fourteen, or forty, useful medicines. One need not neglect pathology or diagnosis, hygiene or physiologic therapy, in order to learn how to apply every means offered by nature or art, to the relief of suffering and the assistance of recovery. You with your science and your skill, with your knowledge of botany and of zoölogy, of mineralogy and of chemistry, search the world over with patient industry to find means by which the physician may be enabled to relieve the distress and to promote the recovery of his patient; and when a certain molecule that promises to be useful does not exist in nature, the pharmaceutic chemist goes into the recesses of his mind and searches it out there and synthetizes it by his skill, and produces it by his mastery of matter and energy, and gives it to us for an additional weapon in the fight against disease and suffering; and for that we and our patients are thankful. We depend on you, therefore, to prepare for us that which exists in nature, and to find for us that which art — or rather science applied in art — alone can furnish.

"And in conclusion, going back to what I said in the beginning, if you pharmacists and we physicians have made mistakes in trade, or in science or in art, let us get together and amend them. Let us get together not for reproach or recrimination, but for mutual encouragement in well-doing. Thus can we strive shoulder to shoulder for the advance of medicine and for the inseparable progress of pharmacy."

THE RELATION OF TUMORS TO INJURIES.

THE discussion regarding the relation of trauma to the formation of tumors is not likely soon to be laid to rest. As a matter of fact, we really know very little about the matter, and dogmatic statements, one way or the other, are unlikely to advance our real knowledge of the subject. From many points of view it is desirable that some consensus of opinion should be reached regarding this matter, primarily as a possible means of prophylaxis, and secondarily in its practical relation, particularly on the medico-legal side. It is questionable whether any expert pathologist is justified in dogmatically asserting that tumor never arises from trauma, nor could the opposite contention be maintained that trauma is an essential antecedent. It is in just such matters as these that the medical profession is placed in an unfortunate position before the courts, wherein legitimate diversity of opinion is emphasized to meet the special ends of the attorneys.

The *Journal of the American Medical Association* has recently discussed the matter from an editorial standpoint, and reaches conclusions which are likely to be generally accepted, indefinite as they are from the necessities of the problem involved. It appears from this analysis, in which the statistics of various observers are considered, that in a certain number of cases the assumption is entirely justified that tumor formation actually follows trauma, but that the vast majority of new growths are quite independent of any such exciting cause. This tentative position naturally excludes any dogmatic statement in an individual case, whether in the court room or elsewhere; but such an expression of ignorance is certainly more desirable than dogmatic assertions unsupported by facts.

In the same number of the *Journal*, Dr. William M. Leszynsky, of New York, reports a case of intracranial tumor which he regards as directly resulting from traumatism. Following a blow on the head, his patient, a young man, developed unmistakable symptoms of brain tumor from which he ultimately died. The autopsy revealed a spicule of bone projecting from the inner table of the skull through the dura. An endotheliomatous tumor was adherent to this spicule of bone and to the dura, but non-adherent to the brain. Dr. Leszynsky concludes that the trauma was the direct cause of the tumor formation. Such a case as this, however, interesting as it is, does not fully meet the requirements of the situation. Had the original trauma not led to the fracture of bone, there is no probability that tumor would have resulted. The new growth was due rather to the continued irritation of the bone than to the original traumatism, and therefore should not be regarded as a clear example of a tumor due to trauma.

It is not likely that the general question will soon be settled. In the meantime statistics should be widely collected and interpreted wholly without prejudice one way or the other.

MEDICAL NOTES.

Unveiling of Memorial Statue of Prof. Joseph Leidy. — The memorial statue of Prof. Joseph Leidy will be unveiled at 3 P.M., Wednesday, Oct. 30, 1907, at the City Hall Plaza (West Side), Philadelphia. There will be addresses by Mr. Joseph Wharton and Prof. Henry C. Chapman, M.D.

Opening of Philippine Medical School. — According to the *Report of the Bureau of Health* of the Philippine Islands the new Philippine Medical School formally opened its doors to students on the 10th of June, and at the present time 54 young men and one young woman are studying the science of medicine along American lines. The medical department of the Santo Tomas University has been engaged in improving its facilities to meet the competition of the new school. A new dissecting room has been planned and is now under construction, and the laboratory facilities have been increased. These are all hopeful signs and all indicate the awakening of the Philippines.

Alvarenga Prize of the College of Physicians of Philadelphia. — The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1908, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered.

Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten, and must be received by the Secretary of the College on or before May 1, 1908.

Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author.

It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award.

The Alvarenga Prize for 1907 has been awarded to Dr. William Louis Chapman, of Providence, R. I., for his essay entitled: "Post-operative Phlebitis, Thrombosis and Embolism."

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Oct. 23, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 44, scarlatina 45, typhoid fever 28, measles 13, tuberculosis 40, smallpox 0.

The death-rate of the reported deaths for the week ending Oct. 23, 1907, was 15.92.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Oct. 19, 1907, was 208, against 206 the corresponding week of last year, showing an increase of 2 deaths and making the death-rate for the week 17.80. Of this number 103 were males and 105 were females; 203 were white and 5 colored; 138 were born in the United States, 68 in foreign countries and 2 unknown; 46 were of American parentage, 145 of foreign parentage and 17 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 45 cases and 1 deaths; scarlatina, 48 cases and 0 deaths; typhoid fever, 24 cases and 7 deaths; measles, 8 cases and 0 deaths; tuberculosis, 29 cases and 19 deaths; smallpox, 0 case and 0 deaths. The deaths from pneumonia were 20, whooping cough 0, heart disease 24, bronchitis 4 and marasmus 2. There were 16 deaths from violent causes. The number of children who died under one year was 47; the number under five years, 62. The number of persons who died over sixty years of age was 30. The deaths in public institutions were 59.

There were 2 cases and 2 deaths reported from cerebrospinal meningitis during the week.

Property Acquired by the New England Hospital. — The New England Hospital for Women and Children has acquired a piece of property in Dorchester, which was formerly the estate of Elizabeth H. D. Shepherd.

Appointment of Dr. H. C. Emerson. — Governor Guild has nominated Dr. H. C. Emerson, of Springfield, Mass., as health inspector of the Hampden District, in place of Dr. Richard M. Benner who has resigned.

DINNER TO DR. CHARLES P. BANCROFT. — As a recognition of Dr. Charles P. Bancroft's twenty-fifth year as superintendent of the New Hampshire State Hospital, a number of his colleagues, many of whom had formerly been associated with him in professional work, gave him a dinner, Oct. 15, at the University Club in Boston.

APPOINTMENT OF DR. HENRY A. COTTON. — Dr. Henry A. Cotton, of the Danvers Insane Hospital, has been appointed medical director of the New Jersey State Hospital for the Insane to succeed Dr. John W. Ward, who has recently resigned. During his stay at Danvers, Dr. Cotton has won for himself an enviable position as a psychiatrist. The hospital will lose much by his departure.

BEQUESTS TO HOSPITALS. — By the will of the late Miss Florence Lyman the following institutions are beneficiaries: House of the Good Shepherd, $50,000; Carney Hospital, $30,000; St. Mary's Infant Asylum, $25,000; St. Vincent's Orphan Asylum, $10,000; Massachusetts Charitable Eye and Ear Infirmary, $10,000; Massachusetts General Hospital, for free beds, $5,000, and several other minor charities. The entire amount of public bequests in the will is estimated at $235,000.

DEATHS FROM AUTOMOBILES. — According to a recent report of the Safe Roads Automobile Association, there have been 41 deaths and 313 injuries in Massachusetts from the careless driving of automobiles in the three months ending Sept. 21. In this same period there have been 211 collisions in which automobiles were involved. It is believed that the numbers here given are incomplete, inasmuch, as the tabulation includes only those accidents which find their way into the papers. The report concludes, from the facts obtained, that reckless driving on the part of automobilists is common, that an organization which shall take active measures to prevent such reckless driving is necessary, and that some radical action should be taken to prevent reckless operators of automobiles from continuing in their work. Fifty cases have been investigated by the association and five have been brought before the criminal court. The work of this association should certainly receive the fullest co-operation, not only of the public at large, but also of automobile owners. It is proposed to bring before the legislature a bill requiring operators of automobiles to pass an examination, and it is hoped also to institute certain tests regarding eyesight and hearing.

NEW YORK.

THE SMALLEST ADULT BRAIN ON RECORD. — In making a post-mortem examination of the body of Daniel Ryan, a watchman forty-six years old, who died suddenly, coronor's physician O'Hanlon and Dr. Larkin, adjunct professor of pathological anatomy in the College of Physicians and Surgeons, discovered a brain which is believed to be the smallest in point of weight ever recorded in a normally intelligent adult. It weighed only 24 oz., or scarcely one half the weight of the average brain of adults of similar size and physical condition, while the convolutions were regular and the color normal, and there was no evidence of disease in any part of the organ.

EDDYITES GUILTY OF MANSLAUGHTER. — On Oct. 10 Edwin M. Watson and his wife, of Moorestown, N. J., were found guilty of manslaughter in failing to provide medical treatment for their son, seven years old, who died in May last from pneumonia and cerebrospinal meningitis. They are Christian Scientists and had the services of an Eddyite healer, but a physician was called in only when the child was *in extremis*. The case was tried at Mount Holly, the county town, before Judge John Horner, who reserved sentence as the defendants gave notice of appeal from the verdict of the jury. The maximum penalty for the offence in New Jersey is stated to be fifteen years' imprisonment.

BEQUESTS TO COLUMBIA UNIVERSITY. — It is announced that Mrs. George E. Wheelock has given $5,000 to the Department of Physiology of Columbia University in memory of her husband, and that Mr. B. M. Baruch has given $5,000 to the Vanderbilt Clinic in connection with the Medical Department.

POLLUTED SHELLFISH FROM NEW YORK AND NEWARK BAYS. — After a careful investigation, the New York Bay Pollution Commission and the Pollution Committee of the Merchants' Association report that approximately 2,000,000 bushels of oysters and clams are gathered annually in New York Bay and adjacent waters, where it is estimated that sewage is emptied to the extent of 1,000,000 gallons a day. Many of these are taken annually from Newark Bay, where the estimated sewage discharge is 450,000,000 gallons daily. It is a common practice to take oysters from the salt water and place them in shallow water at the mouth of some fresh-water stream to be "fattened." According to Dr. Daniel Lewis, recently head of the New York State

Health Department and now president of the metropolitan committee, "there is not a square foot of the waters of the harbor that is not polluted with sewage. New York Bay is in a disgraceful condition, and the waters of the bay on the south shore of Staten Island, where most of the oysters and clams are gathered, are nothing more or less than a whirlpool of sewage." Of several thousand specimens analyzed, Dr. Lewis reports that there was not one which did not show traces of sewage. Commenting on the present conditions, Edward Hatch, Jr., chairman of the Pollution Committee of the Merchants' Association, says: "There is only one inference to be drawn from this custom of harvesting oysters and clams from sewage-burdened waters. It does not take a scientist or physician to draw conclusions as to the result of eating poisoned shellfish. With millions of gallons of sewage being poured daily into the harbor of New York and adjacent waters where oysters are grown and fattened, it must be evident that no healthy shellfish can be cultivated, and the consequent menace to the health of the neighboring communities which are supplied from these sources cannot be questioned."

Dispensing Cocaine without a Prescription. — Charles W. Hitch, a druggist, who has a pharmacy in the Borough of the Bronx, was convicted on Oct. 15, in the Court of Special Sessions, of selling cocaine without a physician's prescription, and sentenced to serve six months in the penitentiary. The defendant had been fined twice before for the same offence. One of the strongest witnesses against him was the Rev. J. B. Curry, rector of St. James Roman Catholic Church, who stated that a score of young men and boys in his parish had been ruined by the cocaine habit. He testified that they had procured the drug at Hitch's store and cited a number of instances in which cocaine had been purchased there without any difficulty, without a prescription. Both Father Curry and Health Commissioner Darlington, who was present and took special interest in the proceedings, pleaded earnestly for a jail sentence in the case.

Obituary.

ACTION ON THE DEATH OF CHARLES FOLLEN FOLSOM, M.D.

At the regular meeting of the Boston Society of Psychiatry and Neurology, Oct. 17, 1907, the following expression of the sentiments of the society on the death of Dr. C. F. Folsom was adopted.

"The committee appointed to express the sentiments of this society with regard to the death of Dr. Charles Follen Folsom begs leave to report as follows:

"Dr. Folsom was one of the original and most valued members of the Medico-Psychological Society, the parent of the Boston Society of Psychiatry and Neurology. His thoughtful contributions were always listened to with the attention and respect accorded to an acknowledged authority, and his continued interest in our meetings was felt by all of us as a stimulus to good work. His public labors were fruitful in many benefits to sufferers from disorders of the mind. Not only was he an admirable secretary of the State Board of Lunacy and Charity, but it was due to the recommendations of the special commission of which he was a member that the present State Board of Insanity was established and the insane removed from the almshouses and placed under the direct protection of the state. His brilliant mind, his fertility of resource in the treatment of disease, his deep sympathy for his patients and devotion to their needs, the far-reaching benefits to the insane of the Commonwealth from his enlightened public work, his warm interest in the labors of his colleagues and loyalty to the claims of friendship so won our regard and admiration that we feel his death as a personal and public misfortune.

1. Fisk urges the use of apomorphine for its expectorant properties. He finds it efficient and harmless, even in relatively large doses, when taken by the mouth. When given by mouth its effects are widely different from those obtained by hypodermic use of the drug. Hypodermically it is a most valuable centric emetic in doses of from one twentieth to one sixtieth of a grain, acting quickly and gently. The possibility of depressing effects should be borne in mind when it is given to children, and strychnine should be combined with it. By mouth it has little emetic effect, but acts as an efficient expectorant in doses of one eighth of a grain every two hours. It does not increase the effect of other narcotics. It should not be used when there is abundant expectoration. Crystalline apomorphine is to be specified, since the amorphous form is uncertain in its effects.

2. Wilhelm Ebstein, of Göttingen, places obesity, gout and diabetes mellitus in one group, that of hereditary diseases of cell metabolism. The close relation of the three diseases is evident, and the frequent occurrence of all in the same subject. All are to be traced to a certain

deficiency in cell activity. The victim of obesity is unable to consume the fatty acids that result from metabolism in the same degree as a normal individual. The cause of gout is to be sought for in a disturbance of the intermediary stage of metabolism, especially that of the nucleins, growing out of inherited tendency. Diabetes shows a deficiency of carbonic acid excretion, the property of this gas to inhibit the action of diastatic enzymes making it a regulator of the formation of sugar from the glycogen stored up in the body. The sugar is more or less completely excreted before it can be assimilated by the organism. These diseases are seen to result from a primary defect of the cells, and each one may be traced to a change in the biogens different in localization and character.

1. Hemoptysis in tuberculosis has for its etiology either congestion or erosion of vessels or rupture of miliary aneurisms. Hemoptysis is much more frequent in cases with chronic heart disease. However, the general assumption that early bleeding is from congestion is incorrect. There are probably minute erosions. The exciting factors are hemorrhagic tendency, aggravation of cough, muscular exertion and mental excitement. Hemoptysis occurs in probably 60% to 80% of the cases of pulmonary tuberculosis and always tends to recur.

2. Hektoen discusses a tabulated summary of the recorded cases of systemic blastomycosis and coccidioidal granuloma. These diseases are caused by closely related varieties of organisms, which are very similar culturally. In living tissue both exist as spherical bodies. However, the organisms of blastomycosis multiply almost wholly by budding, while those of coccidioidal granuloma multiply essentially by endogenous sporulation. Neither forms mycelium in the animal body. Coccidioidal granuloma tends to involve lymph glands, and its nodular lesions resemble the typical specific tubercle. Blastomycosis does neither. The diseases are rare and nothing is known of the circumstances of infection.

5. The foundation of Boston's campaign for clean milk was the adoption of a standard limiting the number of bacteria to 500,000 per cubic centimeter and prohibiting the sale of milk having a temperature over 50° F. By these means unclean milk has been traced to its source. The ultimate aim of cleanly conditions for milk from the cow to the customer and the refrigeration of all milk is hoped for.

7. Leonard considers that the Roentgen technic has been so perfected and that method of diagnosis so firmly established, that no renal diagnosis is complete or treatment rational, where calculus is suspected, without its employment by a competent and experienced Roentgenologist. In a series of 356 cases, the total error has been less than 3%.

11. White and Pröscher in their second communication report the presence of spirochetes in the glands during life in two more cases, one each of acute lymphatic leukemia and Hodgkin's disease. [R. I. L.]

5. Reynolds regards the treatment of sterility in women as less unsatisfactory than it has usually been supposed. One reason why treatment fails of results in many cases is that in not a few the defect is in reality in the husband. Where the woman is really sterile, the sterility may be due to a variety of causes, but in a vast majority of cases it is due to an alteration of the secretions of one or another part of the genital tract, rendering them hostile to the ovum or to the spermatozoa. Such abnormality of secretions may be counted among the remediable causes of sterility. Acidity of the uterine or excessive acidity of the vaginal secretions may occur either separately or in combination, to be detected by testing with litmus. The acidity is due to constitutional disorders, to pelvic congestion or to bacterial activity. In treatment, general dietetic treatment is indicated to correct abnormal constitutional states, depletion by glycerine suppositories to relieve congestion, and disinfection of the vagina by insufflation of protargol powder to produce desquamation of the vaginal lining.

6. Von Ruck calls attention to the diversity of opinions as to the influence of tuberculous ancestry upon the prognosis in pulmonary tuberculosis. He reports statistics which he has gathered bearing upon the question. It has long been taught that tuberculous ancestry renders the prognosis less favorable. More recently, however, certain authors have disputed this, maintaining that tuberculous ancestry even tends to produce a slight degree of immunity. Von Ruck has studied the statistics of the German Imperial Health Bureau and those of the Winyah Sanitarium, and finds in both (the total data comprising over four thousand cases) that tuberculous ancestry was somewhat more frequent among patients discharged as cured than among those who failed to improve.

7. White shows that primary tuberculosis occurs in a certain proportion of all cases of adenoid hypertrophy, probably in about 5%. Thus adenoids, as well as tonsils, are to be considered as important channels of infection in

tuberculosis of cervical glands. They may sometimes also be the channels of infection in the development of pulmonary tuberculosis, through the peribronchial glands, but their importance is probably greater as predisposing causes of infection of the lungs, by means of the catarrhal inflammations of the upper respiratory tract which they produce. [F. W. P.]

1. From an anatomical investigation into the source of the blood supply of the parathyroids, Evans concludes that (1) the parathyroid glands are always supplied by definite parathyroid arteries, which enter them, in each case, at the hilus; (2) the parathyroid arteries, superior and inferior, usually arise from the inferior thyroid, but frequently they take origin from the anastomosing channel between the inferior and superior thyroid vessels; (3) but few if any direct vascular connections normally exist between the parathyroid glands and the connective tissue envelope of the thyroid. In order to preserve the parathyroids in operation upon the thyroid, Halsted advises an operation of "ultra-ligation," *i. e.*, ligation beyond the origin of the parathyroid arteries. After division of the hyoid muscles, the upper portion of the lobe of the thyroid is grasped and traction made forward and towards the middle line. This exposes the superior thyroid vessels, which are tied as close to the thyroid gland as possible. All hemorrhage should be scrupulously avoided, in order that the parathyroid be not obscured. Before and after operations for Graves's disease, Halsted advises chilling or freezing the neck in order to delay, or even prevent entirely, the toxemia which so often follows operation in these cases.

2. Pool reports a case of tetany occurring in a woman thirty-three years of age, on whom he performed partial thyroidectomy, three years after a previous operation on the thyroid had been done. During the operation, the inferior thyroid artery was tied. Four days later tetany occurred in the hands, in the face muscles and in the feet and calves. Some improvement resulted from the administration of Beebe's nucleo-proteid, several attempts at transplantation of fresh parathyroids into the abdominal wall or the lobe of the ear having been without avail. He gives an exhaustive review of the whole subject of tetany following removal of the parathyroids.

4. By the use of positive pressure, through a canula, Green and Maury have been able to perform gastro-esophageal suture by the transpleural route. Dogs were used in the research. The protection of the pleural cavity from infection must be complete. When the point of resection was near the cardiac end of the stomach, this was accomplished by pushing down the gastro-esophageal wound into the abdominal cavity, so that the omentum might apply itself to the wound area, as in any intestinal operation. No difficulty was experienced in keeping the lung well inflated.

5. The authors have investigated the question as to whether, following gastro-enterostomy, solid food leaves the stomach by way of the pylorus or through the artificial stoma. A dog was allowed to swallow a small bullet tied to a string and imbedded in meat. In one instance, this bullet travelled through the stoma and backward through the pylorus again into the stomach. In other instances the food passed by way of the pylorus. Also from their observation of the lacteals after the feeding of fat it would seem that the fat left the stomach by way of the pylorus. These observations, to be made more complete later, bring out the point that a gastro-enterostomy in the presence of a patent pylorus may be functionless.

6. Maury has demonstrated on dogs, that following a gastro-enterostomy by the twine triangular stitch, if the duodenum be closed at a point within about 35 cm. of the pylorus, the animal will die in from seventy to one hundred hours. If this closed duodenal loop be made longer, however, the animal will live. The condition of the stomach and intestines, whether empty or not, is without influence, thereby ruling out death from decomposition of food. It seems probable that death in these cases is due to the absorption of toxic elements in the bile, which are normally rendered harmless by dilution and colloidal suspension in the secretions of the small intestine; as the length of the small intestine from the bile duct to the site of obstruction decreases, the diluting secretions decrease, and the toxicity rises.

7. Blake and Brown find that after total exclusion of a segment of the large intestine, leaving it in the abdominal cavity, it will continue to distend from accumulation of excretions and its walls will hypertrophy. Distention, in a case operated on, continued until perforation occurred with subsequent abscess formation. It is evident, therefore, that total occlusion, even of a segment of the large intestine, is an unwise procedure.

8. The authors show by a series of twenty experiments on dogs that the intestine can propel its contents in an anti-peristaltic direction. They reversed loops of the small intestine of various lengths, and later observed them by direct inspection. Anti-peristalsis was observed both in the large and the small bowel.

9. Leggett reports 31 cases of rectal anesthesia, performed according to the method of Cunningham. A valuable modification of Cunningham's apparatus consists of an exhaust tube, by which the rectum may be emptied at any desired moment. Properly used, this method of producing narcosis is of great value in selected cases.

12. The case studied by Rothstein, and operated on by Ochsner was as follows: A man, twenty-three years of age, presented 108 exostoses at numerous portions of the skeleton. Combined with these, there was pain on suddenly rotating the head; and motion of the right arm and hand and tactile sense of the left arm were somewhat impaired. He could not place his feet exactly where he wished them, especially his right one. This leg dragged more than the other, and the right hip seemed stiff. Neurological examination made it evident that there was a lesion in the right half of the cord, between the base of the skull and the upper border of the fifth cervical vertebræ. Under ether, a large exostosis was found springing from one of the lamina of the axis, and growing into the spinal cord. Two weeks after removal of this, motion began to return in the right half of the body, and since that time, sensation and motion have slowly but gradually improved.

13. De Amezaga reports a case of successful arthroplasty for tuberculosis of the elbow joint in a girl of eighteen. This was done after a previous resection of the joint. As an end result there was a shortening of about

four inches in the affected arm. Rotation and supination were perfect, as were also the motions of the fingers. The joint could be flexed to 35°, and extended to 150½°. The advantages of such an arm over the ordinary flail joint are evident.

15. Stone reports the case of a boy of five years, in whom, following destruction of the tibia by necrosis, he transplanted the fibula with complete functional success. The upper end of the fibula was first attacked and mortised into the lower end of the tibia. Subsequently the lower end of the fibula was split and united to what remained of the lower epiphyseal end of the tibia. This transferred bone increased rapidly in size, so that two years and eight months after the tibia had been removed the leg was functionally good; both external and internal malleoli had been preserved; there was no tendency to either talipes varus or valgus, and there was a shortening of only one and a half inches. [W. C. Q.]

1. Rolleston, in considering the adrenals, speaks first on the functions and histology of the cortex, and then on those of the medulla. As regards the cortex, there are three views: (1) that it is connected with growth, especially of the sexual organs; (2) that it exercises an antitoxic function; and(3) that it plays some part in the elaboration of the internal secretion of the medulla. Of these views by far the most definite is that it is co-related with sexual growth. The cells of the medulla provide a substance — adrenalin — which acts on the sympathetic nerve endings. The pathological relations of the internal secretion of the medulla he divides into alteration in quantity (absence, diminution, or excess), and alteration in quality. Complete absence is met with in Addison's disease; diminution in amount of secretion is found in chronic wasting diseases with low pressure, and in certain acute contagious diseases (especially in children) where there is acute degeneration and hemorrhage into the adrenals. Of excessive secretion little is known. It has been thought that the high tension of some forms of chronic nephritis and arteriosclerosis is due to a hypersecretion of adrenalin. In regard to alteration in the quality of the adrenal secretion little or nothing is known.

9. Morton and Jones report four cases of mammary carcinoma in which there were post-operative recurrences. In each case the trypsin injection treatment was carefully tried. In no case were there any beneficial results, but in two they believe death was hastened and the patient made more uncomfortable. [J. B. H.]

6. Mott discusses the various forms of alcoholic insanity, and the relation of alcohol to insanity in general. He calls attention to the effect of alcohol and syphilis as co-workers in producing mental derangement and insanity, and believes that although alcohol may to a certain extent kill off the weaker types and so improve the race, its effect in increasing venereal disease and especially syphilis is far more important in the opposite direction.

16. Langmead divides patients in whose urine acetone may be found into three groups: (1) those showing no symptoms of acidosis, such as cases of starvation, high fever, gastric ulcer, malignant disease, etc.; (2) those who, while the subjects of other morbid states, have also symptoms of acid poisoning which may to a certain extent be masked by those of the primary condition. Such are patients with diabetes, intracranial disease, sepsis, acute peritonitis, and certain forms of poisoning as morphine and sodium salicylate; (3) patients who suffer from uncomplicated acidosis which *per se* may terminate fatally. Of this there are two forms: (*a*) delayed anesthetic poisoning, (*b*) recurrent, cyclical or periodic vomiting. His remarks are confined to the last group. He reports 5 cases in detail and concludes: (1) Acetone and diacetic acid may be present in the urine in a number of conditions without symptoms; (2) cyclical vomiting and delayed anesthetic poisoning are examples of acidosis of unknown origin; (3) delayed anesthetic poisoning is due not so much to the kind of anesthetic as to the state of anesthesia; (4) the determining cause of acidosis is the accumulation of the precursors of acetone, either from excessive formation or deficient excretion; (5) anesthetics are dangerous to patients who are the subject of acidosis. 2. Nieter reviews an outbreak of typhoid among the nurses in his insane hospital, for which no cause in food or water could be found. In the ward, however, in which the infected nurses worked, an inmate was discovered whose stools constantly contained both typhoid and paratyphoid bacillus and who was undoubtedly the source of infection. The author then reviews the reports of 13 other such outbreaks, where the infection was traced to the stools of an inmate, who had had typhoid years before. He believes that the bacilli remain for years in the gall bladders of the "bacilli carriers," and are thence discharged into the intestine, and evacuated with the stools. In every outbreak of typhoid, especially in institutions where no other cause can be found, a search for such a "bacilli carrier" should be instituted. [There are a number of cases in the literature in which typhoid bacilli have been demonstrated in the gall bladder long after the primary infection.]

3. Ach gives a careful résumé of the early work on lumbar anesthesia by cocaine, which proved far from satisfactory, on account of the high percentage of deaths and permanent paralyses resulting from its use. Since the introduction of stovain, and later of tropacocain, this danger has been greatly lessened, the author having used tropacocain anesthesia in 250 cases without a death, without any permanent bad results, and with only 20% of unpleasant after effects. He describes minutely the technic of the procedure, and the course and duration of the anesthesia. He is convinced that in a large number of cases it is much to be preferred to ether and chloroform anesthesia.

9. Voeckler reports a case of rupture of the liver and pancreas, with operation and recovery. He discusses at length the symptomatology in such cases, and concludes that every case of severe trauma followed by symptoms of "shock," or in which the pain, prostration or vomiting increases, or wherein a shifting dullness appears in the belly, after injury, should be explored at once. The diagnosis in these cases is never easy, and it is safer to operate on a slight suspicion, than to hold off until too late. The author favors packing the rupture, as the quickest and surest method of stopping the bleeding, though in suitable cases deep sutures through the liver tissue may be used. With early surgical interference rupture of the liver should become a less hopeless condition than it is now considered. [R. D.]

1. For several years in Kraus's clinic in Berlin cases of pneumonia have been studied by means of the x-ray. The results of many of these observations are here reported by Jürgens, and a number of illustrative cases are cited. It is pointed out that a shadow may remain for a considerable time after the crisis, indicating that resolution in the lung has been delayed, but eventually the shadow entirely disappears, showing that resolution has been complete. On the other hand in cases in which organization follows the consolidation, the picture is different. Here the intensity of the shadow does not decrease, though its extent may diminish as the newly-formed connective tissue contracts. With delayed resolution there is a very uniform clearing of the shadow, while with organization parts clear up and other parts remain dark. In the former there is usually no fever. Both these conditions may escape detection by auscultation and percussion. The development of a pneumonic process as studied by the x-ray shows some points of interest. In some cases, apparently the exudation may clear up without there being any demonstrable change in the percussion note. Sometimes the process advances very rapidly, at other times slowly and gradually. In some cases about a pneumonic area lines of consolidation may radiate out into the neighboring tissue before the surrounding part becomes uniformly consolidated. It is possible that this may represent extension along lymphatics. The decrease in diaphragmatic movement associated with pneumonia of the upper lobes is very distinctly shown by the x-ray examination. The development of pleuritis with pleural adhesions also can be followed. The development of gangrene and abscess was followed in some cases. In particular one case was studied in which a cavity as large as an apple developed as a result of gangrene, and the healing of this cavity was traced until it entirely disappeared, leaving only a small scar behind. Probably of more interest than the preceding were the observations in regard to the relation of tuberculosis to apical pneumonia. It has been long recognized that the prognosis with pneumonia of the upper lobes is not so good as when the lower lobes are involved, and that particularly in these cases is tuberculosis apt to follow the pneumonic process. The exact relation of the bacillus tuberculosis to the pneumococcus in pneumonia has remained a matter of dispute. By means of the x-ray Jürgens has been able to follow a pneumonic process in its resolution and see subsequently the gradual extension of a tuberculous focus in the same area. At times after the pneumonic process had almost disappeared the lung field would remain clear for several weeks and then there would be a quite rapid extension from a small area of consolidation, and this was shown by sputum examination to be tubercular in origin. This author believes that in most cases the tubercular infection has preceded the pneumococcus infection, and that the tuberculosis spreads rapidly as a result of the lowered resistance of the tissue produced by the preceding pneumonia.

2. Gigon contributes a third study of the laws of sugar excretion in diabetes mellitus. This is a careful metabolism study of a case of diabetes, during the course of which the ducts of the pancreas became obstructed with calculi. This case, in which no pancreatic secretion reached the intestinal tract, showed less disturbance of absorption than was to be expected from a study of previous cases. This is possibly due to the fact that in other cases other conditions than pancreatic obstruction worked in conjunction with the pancreatic obstruction to increase the disturbance of absorption. The excretion of fat in the intestinal tract in this case showed great variations from time to time. However, the amount of soap present was continually decreased in comparison with the normal, and the amount of fatty acids always exceeded the amount of soaps. Pankreon administered in this case produced only a transitory improvement in the condition.

4. Plesch describes a new apparatus for estimating the hemoglobin of the blood, for which he claims great accuracy combined with ease of application. The principle of the apparatus is the comparison side by side of rays of light which have passed through a standard solution and a solution of the blood to be tested respectively. The standard solution is carbon monoxide hemoglobin and carbon monoxide is passed through the blood to be tested. Each is diluted 250 times, as the most accurate comparisons can be made of paler colors. The depth of the layer of solution to be tested is varied until it gives the same shade of color as the test solution, and the per cent of hemoglobin is calculated from the thickness of layer

necessary to give this. The rays of light passing through each solution are brought side by side by an ingenious arrangement of prisms. With the instrument the total blood mass of the circulating blood can also be calculated by comparing the oxygen-absorbing power of the hemoglobin before and after the inspiration of a measured quantity of carbon monoxide. [The apparatus seems applicable to more exact investigations rather than to routine clinical use.]

5. In a study published in 1904 Arneth subdivided the neutrophilic leucocytes into five classes according to the irregularity of their nuclei. In class I he placed the neutrophiles with round or only slightly indented nuclei, and in class V those with nuclei showing five chromatin masses as the extremes of his classification. He showed that in infectious diseases as compared with the normal there was an increase in the percentage of leucocytes of the simpler forms. In the present study Bourmoff and Brugsch have confirmed these findings for a number of severe infections like tuberculosis, scarlet fever, pneumonia, erysipelas and tetanus. They find that the degree of change does not always run parallel with the severity of the disease. These authors, however, do not agree with Arneth that the change represents an actual change in the leucocytes of the circulation, but they think it is rather a result of the fixation process dependent on the fact that in these diseases the nuclei are larger and plumper, and consequently not as prone to shrinkage during fixation and staining as under normal conditions. The change then to them is an index of chemico-physical changes of the medium in which the leucocytes circulate. However, further biologic studies of these factors are promised with the hope of attaining a better knowledge of the blood changes in infectious diseases.

6. Kuhn reports here a case of carcinoma (recurrent inoperable cancer of the breast) treated by injections of pancreatin into the tumor masses. The result of this was very extensive destruction, not only of tumor but of surrounding tissue, with a rather speedy fatal end. This case does not speak strongly in favor of the efficacy of pancreatin treatment. In the discussion, Kuhn speaks of favorable results which have been obtained in Leyden's clinic by the use of pancreatin given by mouth in cases of cancer of the stomach. Here a decrease in the pyloric obstruction was obtained, and though the cases are too few in number for very general conclusions, it would seem that pancreatin given thus in one to three teaspoonful doses might be of some value. In another case of cancer with cutaneous nodules the application of radium appeared to have some destructive action on the cancer cells, but this was not very marked.

7. In 27 cases of typhoid Meyer obtained the typhoid bacillus from the circulating blood in 26 cases. Of particular interest in this series are 2 cases, one complicated by pneumonia, in which the pneumococcus and typhoid bacillus were obtained from the blood culture, the other a case of typhoid following child-birth in which both the streptococcus and typhoid bacillus were obtained. In a case resembling typhoid clinically in every respect a pure culture of bacillus alcaligenes fecalis was obtained from the circulating blood. Tests of the typhoid organisms obtained from these cases showed greater pathogenicity for animals when derived from cases of severe typhoid as compared with those from mild cases.

8. In a study of diabetes mellitus Geelmuyden obtained maltose from the urine in a number of his cases. He considers maltosuria not a rare, but a common, accompaniment of glycosuria in diabetes, which is contrary to most of the findings of other authors. [H. A. C.]

Correspondence.

WARM AIR FOR INFLATION OF THE EAR.

BOSTON, Oct. 16, 1907.

Mr. Editor: This letter is written to advocate the use of warm air for the inflation of the ear, instead of air the temperature of the room. In secretive middle ear conditions it is especially valuable. The sensation of warm air is agreeable. Air warmed over a gas burner is injurious to an ear.

I have an air chamber, that fits on a bull's-eye electric nose and throat light, perforated at the side to receive the tip of the Politzer bag. The temperature can be tested on the face.

I have in view a more practical and scientific method of using warm air. I realize that it is not an original thought, but certainly it is not generally employed and its advantage is considerable.

Respectfully yours,

ARTHUR J. SHAW, M.D.

LETTER FROM PARIS.

[*From our Special Correspondent.*]

ON THE ABORTIFACIENTS OF SYPHILIS: ATOXYL AND CALOMEL.

PARIS, Oct. 8, 1907.

Mr. Editor: There are glad tidings in the air for the festive bummer, the knight-errant with the *insouciant* device, "Any port in a storm," with whose untiring efforts to relieve the tedium of life we are so often called on to sympathize, and from whom we try to drive off the Neisser, Unna and Schaudinn moths when they settle on him in the course of his convivial endeavors.

For the paternal Metchnikoff, to whom already he owes a statue for the gift of a divine and preservative balsam to be applied during his leisure hours of repentance, has now laid him under an even heavier debt of gratitude.

But first let me give the latest and improved formula of the first-mentioned sinner's *vade mecum*. It appears that the original 25% to 33% calomel in lanoline salve would not slip, "lacked unctuosity," to use the official term, so great was the proportion of its solid contents. Consequently a different formula has to be devised, and the following, which has now been adapted, is said to fit all requirements: Calomel, 33; lanoline, 67; vaseline, 10. This, we are told, can give points in slipperiness even to the uncertain banana-skin; and we now have really no longer any excuse for allowing the pallid treponema to get the upper hand of us.

But even this revised edition of the original salve is not perfect, perfection being not of this earth. It is, of course, a comfort to be assured that the ointment now slips all right; but the method itself leaves much to be desired in a number of respects. It is all very well to inoculate a macacus ape, rub in the pomatum, and demonstrate that the virus does not develop; *you know where to rub!* But how is the ordinary confiding mortal, "the man in the street," to know where to rub? Or is he to inunct the entire genital region? And in that case would not such a generous application risk producing skin inflammation, or mercurial intoxication?

Furthermore, to have a fair chance of proving efficacious the inunction has to be made *during the first few hours* after the infectious contact, under penalty of arriving too late and of finding that the elusive spirochetæ have already moved on.

Again, the lapsers from the paths of virtue are not all of the male sex, evidently: there are the co-respondents, to use the legal phrase; and whereas it may occasionally be feasible for a man to single out a point of entrance for the virus in some slight excoriation, this becomes practically an impossibility in the other sex.

Consequently, it is clear that there are several important drawbacks to the calomel salve preservative, and they have naturally not escaped the acumen of MM. Metchnikoff, Roux and Salmon, of the Pasteur Institute, who now hope that a more satisfactory method has been discovered in the hypodermic use of atoxyl, or anilarsinate of soda, a combination of aniline and arsenic, the latter being the predominating ingredient. But this point requires some development.

When it was found that atoxyl was efficacious against the trypanosoma of sleeping sickness, the idea immediately arose of testing the action of this remedy in syphilis, on account of the close similarity between the spirilla of the

two diseases; and about three months ago Hallopeau, of the Paris Faculty, made a report to the Academy of Medicine of this city, on the generally favorable results of this treatment in upwards of 150 cases of syphilis. Since this is probably somewhat of a novelty, and you may not yet be familiar with the method, I will give a rapid summary of his *modus faciendi*, and of the principal details of this treatment.

He always uses a 10% solution in hypodermic injections in the gluteal regions. With a patient of average size and health, he gives first, at an interval of two days, two injections of 0.75 cg. each of atoxyl; then, at intervals of three days, four injections of 0.50 cg. each. This constitutes a series, and must be followed by a rest. Thus:

First day,	hypodermic injection	0.75	cg.	of atoxyl
Third day,	"	" 0.75	"	"
Sixth day,	"	" 0.50	"	"
Ninth day,	"	" 0.50	"	"
Twelfth day,	"	" 0.50	"	"
Fifteenth day,	"	" 0.50	"	"

The drug is eliminated by the urine, in which as a general thing no trace of it can be found two weeks after the completion of such a series. Treatment proceeds, consequently, by series of six injections, taking two weeks, separated by intervals of two weeks' rest.

From a pharmacological point of view, now, there are several important details, to which the closest attention is invited. The drug deteriorates spontaneously at the end of a short period; in two weeks it breaks down, and may form products of greater toxicity. It must consequently only be used when freshly prepared, as it will not keep. The same thing occurs if the drug is heated to 100° C. for a while; it cannot therefore be sterilized in the usual manner. Hallopeau has used two varieties of atoxyl, one of German origin, the other of French; the German appears to be much more toxic than the French, though this may depend simply on the mode of preparation, and also on the fact that the German product can scarcely be procured fresh whenever wanted.

Clinically one feature must never be lost sight of: contrary to what might be supposed from the name, atoxyl is a poison, and it belongs to the group of *cumulative* remedies; trouble from its use is then bound to follow with everybody, if its dose is too great, or if it is given for more than a certain length of time. For these reasons the series must be short, and interrupted by periods of rest to allow for elimination. During the series a patient must be closely watched, and the treatment interrupted at the least sign of intolerance, — returning again later on, if nothing occurs.

The signs of intolerance of atoxyl are: gastro-intestinal pain, nausea or vomiting, general distress, disagreeable sensations in the limbs, dysuria, loss of consciousness and algidity. They are usually slight, and pass off when the remedy is stopped; but in some few cases may be very severe, and cause anxiety for forty-eight hours or more. Great care must be taken to be on the lookout to catch the first symptoms of intolerance, as they appear with the greatest suddenness, as though some rapid dissociation of the drug took place after it had accumulated in the system to a certain point.

On account of the severity and great suddenness of appearance of atoxyl intolerance, it is necessary to proceed with caution, give moderate doses, at proper intervals, and by series. In determining the proper dose, the age, size and weight of the patients must be considered, as well as their general condition of health. If there is heart or kidney disorder, or a cachectic condition, great circumspection in dose must be observed.

Atoxyl forms a third weapon in our hands against syphilis, not one designed to dethrone the other two, but one to be used concurrently with or in succession to its seniors. There is no more incompatibility between atoxyl and mercury than between mercury and iodide of potash.

So much for atoxyl as a *curative* remedy in syphilis; now for its qualities as a *preventive*, — the point that interests us more directly to-day, and which, if it turns out to be true, seems destined to revolutionize matters.

Experimenting on the macacus ape with injections of atoxyl, Metchnikoff has found that when given hypodermically *after* the appearance of a chancre at the point of syphilitic inoculation, it does not prevent the evolution of the disease; *but that, when used earlier, before the chancre has appeared, during the incubation interval, even so long as two weeks after inoculation, — no visible signs of syphilis manifest themselves!* This is the really interesting point in this whole affair.

The apparent reason why atoxyl has time to act, during the long incubation period, is that the treponema does not adapt itself readily to the human system, and that a certain length of time is necessary for it to be able to multiply to any appreciable extent.

Being myself a little hazy about the exact personality of the macacus, I consulted Webster, who says: "The macacus is a genus of apes characterized by having short tails and very prominent eyebrows." It at once becomes clear why Metchnikoff has used this special animal for his experiments, as its relation to man must be very close: we could most of us at a pinch put our hands on fellow-beings who are, in our opinion, apes with short tails and very pronounced eyebrows! Still, in spite of this close analogy, and of the apparent success of the method among our brethren, the pithakoi, the remedy has not as yet won its spurs as an abortive of syphilis in man, so far as I know. But certainly no great interval will elapse before any practitioner so desirous can find an opportunity of testing it for himself.

Think of the comfort it is going to be, to both physician and patient, to have this plank of salvation to tender to these men when they turn up a few days after exposure, half crazed with suspense and threatening suicide through anxiety! What a mercy it will prove if only to keep them quiet, to be able to say that even if they have caught syphilis we have now a means of heading it off before it comes to maturity.

There can be little question as to the practical importance of this discovery. In spite of the meritorious efforts of the many well-intentioned people who are striving to open the eyes of the young to the dangers of irregular life, and to stem the tide of the social evil, I question whether their results will amount to much. At most will they frighten a few timid neurasthenics away from the Scylla of vice into the Charybdis of self-abuse. For they have here to deal with the greatest factor in life: the whole world revolves about the sexual pivot, and there is no use of shutting the eyes to this fact; what then can their feeble voices really hope to accomplish in face of a problem of such magnitude as this?

So long as human nature remains as it is, and we continue to be no more than the descendants of father Adam, so long will such men as Metchnikoff be necessary for the public weal. The ingenuity of man will continue to extract different kinds of alcohol from the fruits of the earth, each race according to its climate; and frequentation of the society of Bacchus leads inevitably to a search after other members of the ancient theogony, — Mars, and Venus in particular, — with the results that always have followed, do follow and will continue to follow, *in saecula, saeculorum*, — the lock-up, hospital, and physician's office! This is why, at least till further notice, we cannot be provided with too many remedies of the order of Hydrarg., KI, atoxyl and calomel.

In fact, so far from improving, the world's morality seems likely to grow worse, on account of the steadily increasing difficulty of marriage among civilized people. Life is now not easy; to most men the expense of maintaining a family grows apace, and marriages occur at a point in life that is steadily receding. It would seem, then, that illicit intercourse between the sexes can do nothing but increase progressively.

To what a degree this can be carried in civilized countries can be realized by a glance at the state of affairs reported a while ago in the city of Toulouse, where, during a given period, out of a total of 194 births, 41 were legitimate, and 153 illegitimate! We in Paris thought we were doing pretty well with an illegitimate proportion of between 25% and 30%; but that is a mere circumstance when placed beside Toulouse's record *of over 75%!*

"Spectator."

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED OCT. 9, 1907.

STONER, G. W., surgeon. Directed to proceed to Montreal, Quebec, and eastern Canadian stations for special temporary duty. Oct. 4, 1907.

WILLIAMS, L. L., surgeon. Detailed to represent the Service at the Sixteenth Annual Meeting of the Association of Military Surgeons, Norfolk, Va., Oct. 15–18, 1907. Oct. 3, 1907.

STONER, J. B., surgeon. Granted leave of absence for one month from Oct. 14, 1907. Oct. 4, 1907.

WERTENBAKER, C. P., surgeon. Detailed to represent the Service at the Sixteenth Annual Meeting of the Association of Military Surgeons, Norfolk, Va., Oct. 15–18, 1907. Oct. 3, 1907.

SPRAGUE, E. K., passed assistant surgeon. Granted leave of absence for five days from Oct. 15, 1907. Oct. 9, 1907.

MCMULLEN, JOHN, passed assistant surgeon. Granted leave of absence for three days from Aug. 17, 1907, under paragraph 191, service regulations.

GRUBBS, S. B., passed assistant surgeon. Granted leave of absence for five days from Oct. 5, 1907. Oct. 4, 1907.

GRUBBS, S. B., passed assistant surgeon. Granted extension of leave of absence for three days from Oct. 10, 1907. Oct. 7, 1907.

PARKER, H. B., passed assistant surgeon. Granted leave of absence for three days from Aug. 11, 1907, under paragraph 191, Service regulations.

LLOYD, B. J., passed assistant surgeon. Leave of absence granted Passed Assistant Surgeon Lloyd for twenty-one days from Aug. 5, 1907, revoked, and leave of absence granted for one month from Aug. 14, 1907. Oct. 7, 1907.

WARD, W. K., passed assistant surgeon. Granted leave of absence for one day, Aug. 17, 1907, under paragraph 191, Service regulations.

FOSTER, A. D., assistant surgeon. Directed to report to Chief Medical Officer, Ellis Island, N. Y., for duty. Oct. 4, 1907.

COLLINS, G. L., assistant surgeon. Granted leave of absence for one day. Oct. 5, 1907.

HALLET, E. B., acting assistant surgeon. Granted leave of absence for three days from Oct. 10, 1907. Oct. 9, 1907.

KENNARD, K. S., acting assistant surgeon. Granted leave of absence for one day, Aug. 30, 1907, under paragraph 210, Service regulations.

NAULTY, C. W., Jr., acting assistant surgeon. Granted leave of absence for two days from Oct. 15, 1907. Oct. 4, 1907.

RAY, D. G., acting assistant surgeon. Granted leave of absence for seven days from Oct. 4, 1907, under paragraph 210, Service regulations.

RAY, D. G., acting assistant surgeon. Granted leave of absence for four days from Oct. 11, 1907. Oct. 8, 1907.

WETMORE, W. O., acting assistant surgeon. Granted leave of absence for one day in August, 1907, under paragraph 210, Service regulations.

BOARD CONVENED.

A board of medical officers was convened to meet at Baltimore, Md., Oct. 10, 1907, for the physical examination of a cadet in the Revenue-Cutter Service. Detail for the Board: Surgeon L. L. Williams, Chairman, and Passed Assistant Surgeon J. T. Burkhalter, Recorder. Oct. 9, 1907.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING OCT. 12, 1907.

H. L. DOLLARD, assistant surgeon. Detached from the Naval Hospital, Newport, R. I., Oct. 15, and ordered to the "Rhode Island."

H. F. HULL, assistant surgeon. Ordered to the Naval Hospital, Newport, R. I., Oct. 15.

B. F. JENNESS, passed assistant surgeon. Detached from the "Constellation" and ordered to the "Glacier."

R. E. LEDBETTER, passed assistant surgeon. Detached from the "Glacier" and ordered home to wait orders.

H. D. WILSON, surgeon. Detached from the "Dixie," when placed out of commission, and ordered home to wait orders.

SOCIETY NOTICES.

THE BOSTON SOCIETY OF EXAMINING PHYSICIANS AND SURGEONS. — The next meeting of the Boston Society of Examining Physicians and Surgeons will be held at the Parker House, on the evening of Oct. 30, 1907. A dinner will be served at 7 o'clock. The business meeting will be called to order at 8.30. In view of recent criticisms of medical experts based upon cases outside of this Commonwealth, the society will take for discussion "The Medical Witness in the Courts of Massachusetts," and the following have been invited to attend and to participate in an informal discussion of this subject: Melvin O. Adams, Esq., Herbert Parker, Esq., Thomas W. Proctor, Esq., Samuel M. Child, Esq., E. P. Saltonstall, Esq., Henry F. Hurlburt, Esq., Hon. John A. Sullivan, Wm. B. Sprout, Esq., J. Porter Crosby, Esq., James P. Magenis, Esq.

CHAS. THEO. CUTTING, M.D.,
Secretary.

THE NORFOLK DISTRICT MEDICAL SOCIETY. — A stated meeting will be held at Masonic Temple, 171 Warren Street, Roxbury, on Tuesday evening, Oct. 29, 1907, at 8 o'clock. Communications: "The Law and the Doctor," Edward G. Morse, M.D.; "Lawyers, Doctors and the Courts," Arthur D. Hill, Esq., and Charles F. Jenney, Esq. The discussion will be opened by Dr. George W. Gay, President of the Massachusetts Medical Society. Collation.

The Board of Censors will meet for the examination of candidates for admission to the Massachusetts Medical Society on Thursday, Nov. 14, at 2 P.M., at the Norfolk House. Fellows will please send to the secretary the names of persons who wish to join the society.

WILLIAM H. ROBEY, JR., M.D.,
Secretary.

RECENT DEATH.

DR. THOMAS A. YORK, of Brooklyn, N. Y., died on Oct. 17, at the age of thirty-eight years. He was graduated from the Long Island College Hospital in 1901, and was for some years in the service of the Health Department in Brooklyn.

BOOKS AND PAMPHLETS RECEIVED.

The Development of the Human Body. A Manual of Human Embryology. By J. Playfair McMurrich, A.M., Ph.D. Third edition, revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1907.

Gout, Its Pathology, Forms, Diagnosis and Treatment. By Arthur P. Luff, M.D., B.Sc., F.R.C.P. (Lond.). Third edition, New York: William Wood & Co. 1907.

Bilharziosis. By Frank Cole Madden, M.D. (Melb.), F.R.C.S. (Eng.). Illustrated. New York: William Wood & Co. 1907.

Immune Sera. A Concise Exposition of Our Present Knowledge Concerning the Constitution and Mode of Action of Antitoxins, Agglutinins, Hæmolysins, Bacteriolysins, Precipitins, Cytotoxins, and Opsonins. By [illegible] Sherrick Boldman. Second edition, rewritten. Illustrated. New York: John Wiley & Sons. London: Chapman & Hall, Ltd. 1907.

THE SUPERIORITY OF PRIMARY OVER SECONDARY CESARIAN SECTIONS, AND THE FEASIBILITY AND ADVANTAGES OF A PREDETERMINATION OF THE METHOD OF DELIVERY.

BY EDWARD REYNOLDS, M.D., BOSTON.

WHEN the forceps were first invented it was regarded as an instrument of last resource, and even the simplest forceps operations were considered exceedingly dangerous. Its use has been gradually extended until it is to-day employed to forestall exhaustion, and in its lesser applications, at least, for the mere lessening of suffering. We are living through a somewhat different but in some respects similar development of the Cesarian section. Its ancient use was for the preservation of the child after the death of the mother. Its revival after the introduction of asepsis was with the idea of lessening the fetal death-rate with but little added risk to the mother. It has now come to be regarded as furnishing in certain difficult cases the safest method of delivery for both mother and child. An inquiry into the circumstances under which it is least dangerous seems appropriate to the spirit of the times.

Each man must be guided in the end by the results of his own experience and the experience of those whom he personally knows and trusts. That in my own experience I have escaped without mortality is, I think, due to the fact that the majority of my operations were done before labor, and that only three could by any stretch of classification be considered late; but I was early struck by the, to me, undoubted fact that both the discomforts which my patients went through during convalescence and my own anxieties therefrom were closely proportional to the length of labor which they had endured before operation. My series (29, now 30, cases without mortality) is, however, too short to carry conviction upon this point to others by a mere recital of the cases. The statistical method of inquiry into the results of others whose personalities are not directly known to us, and of whose cases we have not had personal cognizance, is capable of great abuse and is often misleading, yet it cannot be entirely discarded. It is misleading when conducted upon a series so small that the element of chance is not eliminated, and when used to elucidate points of such delicacy as to lie within the very wide limits of error with which it is necessarily afflicted. It is moderately trustworthy when based upon large numbers of cases, confined to broad lines of inquiry, and attested by sweeping differences in results.

The value of any statistical inquiry must, moreover, rest so entirely upon the spirit and methods under which it was conducted that it is proper that any statistical argument should be prefaced by a statement of the method employed in preparing it. The table which I propose as a prelude to my own observations upon this subject was prepared after the following method: A library assistant, who was uninformed of the points involved, was requested to collect from the literature of the world all the papers which contained case reports of Sænger Cesarian sections done within the last ten years by operators who had had at least five cases. These original reports were then submitted to me. From them were eliminated all cases in which the section had been performed for placenta previa, eclampsia, carcinoma or other new growths, or complicated by other operations having a mortality of their own, such cases being plainly inapplicable to an inquiry into the mortality of the Cesarian section when used for mechanical obstruction and as an alternative to the intrapelvic operations. Cases involving operations upon the tubes or ovaries for the prevention of subsequent fertility were not excluded, these being regarded as at times an intrinsic part of the performance of the Cesarian section.

The cases so selected were then divided for the purpose of this inquiry into three classes: 1. Primary sections, those performed before the beginning of labor, or with the advent of the first pains. 2. Secondary sections, those performed after a certain amount of labor had demonstrated its probably unsatisfactory character, but before exhaustion had set in, and before it had become definitely established that the natural powers would fail to effect the passage of the brim. 3. Late sections, those performed after definite arrest of the head at the brim.

It is at once evident that while the line between primary and secondary sections, so defined, is a perfectly clear one, that between the secondary and late sections is, under the definition, indefinite; and especially so in cases reported in the abstract by others. In separating the cases into their respective classes, I therefore assigned to the secondary section only those cases in which it was definitely stated that the operation was done during the first stage of labor, or that the os was of less size than a fifty-cent piece, putting into the class of late sections all doubtful cases, all cases in which the os was more widely dilated, all cases in which labor had endured for twenty-four hours, or in which it was stated that strong pains had been present for more than eight. Thus many comparatively favorable cases were without doubt unfairly assigned to the unfavorable late class, by which the mortality of this class of late sections is undoubtedly represented as less than it in fact should be, and also the secondary sections are restricted to include only the most favorable of all the operations done during labor; but I hope that you will feel that the final argument is strengthened by this discrimination against the results which my personal experience had led me to expect. I was further careful to assign every case to its final position before ascertaining its result for mother or child.

There were left for analysis 289 cases by 20 different operators. Of these 82 were operated upon before labor began, 158 early in labor, and 49 after the failure of the natural powers was

established. The 82 cases done before labor yielded one death, a mortality of 1.2%. The 158 cases done early in labor showed 6 deaths, a mortality of 3.8%. The 49 cases done after the arrest of the head, or after an unduly long first stage, showed 6 deaths, a mortality of 12%.

Considered in the most superficial way this very marked variation in mortalities is just what should have been expected *a priori*, *i. e.*, it shows that when the section is performed for purely mechanical indications, its mortality is proportionate to the amount of labor which has been endured before operation.

The Cesarian section before or during labor seems not inaptly comparable to an operation for appendicitis in the interval or during the attack. It is, perhaps, more strictly comparable to the performance of a simple abdominal operation upon individuals selected at different points during the progress of a Marathon run or previous to the start. Would any one doubt that if a number of candidates for a Marathon run were divided into classes and subjected to a simple abdominal operation, say the removal of a normal appendix, some before the start, some after the finish, and some at differing periods of the race, that the mortality would be higher among those who were operated upon in an exhausted condition at the finish than among those who underwent the same performance before making the start? The mortality in this case, as in the sections during labor, would probably be roughly proportionate to the amount of exhaustion which the individuals had undergone. But it is not safe to reason from analogy nor upon *a priori* grounds. It is better to adhere to facts, and an inquiry into the causes of death in these 289 women subjected to the Cesarian section at different periods of labor is exceedingly interesting.

The only death among the 82 primary operations was due to an accidental failure of technic in combination with the in competence of an assistant. This death occurred in a case operated upon nearly ten years ago, in which the uterus was sutured with catgut, which has since been generally admitted to be an improper material for use in the uterine suture of the Cesarian section, on account of its liability to become untied during the alternate relaxations and contractions of the uterus. The patient collapsed a few hours after labor, at a time when the operator was at a distance in attendance upon another case; an assistant saw her, and pronounced it a mere nervous faintness needing no treatment. She died shortly afterward and at the autopsy the uterine sutures were found untied and the abdomen full of blood. The operator himself calls it an unnecessary death due to a mistake in technic and the incompetence of an assistant. This death would hardly occur to-day, but for the sake of fairness must be left to stand as the only mortality among this long list of primary cases. It is to be noted that there was no case of peritonitis. This mortality is not only in quantity but in etiology also in strong contrast to that of the cases operated on during labor.

Although the 158 secondary cases (those done early in labor) were operated on by the same operators and under the same conditions, their mortality was wholly due to infection, — all six fatal cases died of peritonitis; and among the 49 late cases, under the same conditions, 3 of the six deaths were reported as due to peritonitis, 2 were reported under the word "infection," and one as due to thrombosis and embolism during convalescence. Only one of these fatal cases had been examined before it came under the care of the operator. In the others the occurrence of infection may be explained variously, *i. e.*, as due to contamination during labor (although in many of them the membranes were unruptured), as due to a lowered resistance from exhaustion, or as the results of a peculiar susceptibility of the peritoneum after long labor. I do not think that in the present condition of our knowledge we can discuss this question with any degree of scientific certainty, or from any standpoint other than the beliefs of the individual disputant. The facts remain that the only death in the cases operated upon before labor was from an accidental and preventable cause; that the cases operated upon during labor by the same operators showed a mortality which was due throughout to infection and which rose steadily in percentage in proportion to the length of labor endured before operation.

Are the following three conclusions then unfair, even when we remember all the uncertainties of the statistical method?

First: It is clear that the mortality of the primary section is less than that of the section performed during labor.

Second: It seems also clear that the section performed early in labor is safer than that undertaken after the failure of the natural powers.

Third: It is desirable that cases which are to be subjected to the Cesarian section should be selected as such in advance of labor, whenever the conditions make this possible.

It is a severe arraignment of the obstetrics of the last few years that it has so generally failed to appreciate the desirability of making the decision for or against the Cesarian section in advance of labor, and that its literature shows an absence of any sustained effort to make this decision generally possible. Progress has been made, cases with clear indications are now generally operated on in advance of labor, and the doubtful class which is still commonly submitted to the so-called test in labor is becoming smaller, but it is to be hoped that this unsatisfactory and always dangerous test will, in the end, be entirely superseded and laid aside. This would be accomplished at once if the profession generally believed that it is possible to predict the result of labor in advance with sufficient accuracy to warrant action. Some few obstetricians are already convinced that the amount which can be accomplished in this direction is much greater than has been generally supposed, and that our power in this direction is already sufficiently great to be of practical use in certain classes of cases.

Success in predicting the result of natural labor to be expected in a given case is dependent upon a capacity for estimating in advance each of the three great mechanical factors in labor, *i.e.*, the obstacle offered by the pelvis, the amount of the maternal muscular powers, and the characteristics of the head. Each of these must be estimated separately, however, and the result obtained by a comprehensive judgment based upon all three.

The amount of the pelvic obstacle is too often spoken of as though it were a mere matter of size obtainable by measurement; in reality the amount of the pelvic obstacle is much more a question of its shape, or rather of the influence of its shape upon any diminution of its size. Some abnormal variations in the shape of the pelvis offer rather less mechanical obstacles than are afforded by normally shaped pelves of the same size or conjugate; other variations create obstacles much greater than those of a normal pelvis of the same size. We are, in fact, too apt to speak of the "contracted pelvis," as though it were merely diminished in its diameters, when we should speak of the "deformed pelvis" which alters the mechanism of labor, and so makes any diminution of its diameters a matter of greater importance. It is necessarily beyond the scope of this paper to enter into any extended discussion of the subject of deformities of the pelvis, but the main points which I wish to make,— that the estimation of the amount of obstacle to be expected from a given pelvis is quite as dependent upon a knowledge of its shape as upon its mere size; and of the extent to which a diagnosis of its shape depends upon an extended examination of the patient rather than upon mere measurements, — may be illustrated sufficiently well by using two of the more common forms of difficult pelvis as examples.

Among the most common of all the difficult pelves is that known as the cylindrical or justo-minor type. From a mechanical point of view the leading characteristic of this pelvis is that it is long in proportion to its size and that it is rather straight and longitudinally erect, *i.e.*, the inclination of the brim to the horizon is usually less than normal, the symphysis is erect, and the sacrum is straight and erect.

The longitudinal curve of the sacrum is less than normal, the promontory is high and the ilia are also very erect, the false pelvis flaring less than normal. The transverse lines of the pelvis are highly curved. The inlet is very round and the iliac crests are highly curved, the difference in length between the interspinal and intercristal diameters being marked. A line connecting the anterior superior spines is higher above the pubes than in the normal pelvis.

With these peculiarities is correlated of mechanical necessity a lessening of the antero-posterior curves of the whole spine. The lumbar region is flat, and the relations between the acetabula and the promontory are such that the body weight is borne along a line which forms a less angle with the upper part of the pelvic axis than in the normal pelvis. The hips of such a woman are usually high and, unless disguised by fat on the outer aspect of the pelvis and thighs, are apt to have a narrow appearance. The legs are straight, and both pelvis and skeleton as a whole are more truly neutral or infantile than either feminine or masculine in type. Although no positive rule exists, such women are apt to begin menstruation late, and to have small uteri with long pointed cervices. The high degree of obstacle afforded by this pelvis in proportion to its size is due to the fact that the obstacle continues throughout almost the whole of the bony canal, the relative shallowness of the longitudinal curves making the middle portion of the pelvis but little more roomy than the superior and inferior straits. If the Cesarian section has been ruled out, this form of pelvis is better adapted to forceps or craniotomy than to any other operation. Version is but seldom successful in justo-minor pelves after forceps have failed, and in this form of pelvis pubiotomy and symphyseotomy are especially apt to be followed by extensive lacerations of the soft parts, owing to the fact that the head meets with resistance throughout almost the whole length of the pelvis.

A hint as to the existence of this pelvis is afforded by the history of late sexual development and by the evidences of it observable in the body as a whole. These are, however, not infallible guides. If an examination of the figure standing, and with the corsets removed, demonstrates the presence of a straight spine and sacrum, with an ill-marked intergluteal fold and comparatively horizontal, sharply curved iliac crests, with the anterior spines high above the symphysis, — all this is strongly corroborative evidence. If this is confirmed by the relation between the interspinal and intercristal diameters as obtained by measurement, and by the shallowness of the longitudinal, and exaggeration of the horizontal, curves, as obtained by internal palpation of the sacrum and lateral walls of the pelvis by the fingers within the vagina, the diagnosis of this form of pelvis may be considered established. We have then to estimate from the results of all these examinations the degree of its alteration in the direction of this deformity, in order to estimate the amount of difficulty which is to be expected in labor from its size as estimated from the length of the conjugate taken by measurement.

Another much neglected but very common and highly important pelvis, which has, so far as I know, received no generally accepted distinctive name, is that of which the leading mechanical characteristic is its excessively curved axis. This pelvis is in many respects the opposite of the justo-minor pelvis. The inclination of its brim to the horizon is excessive, the direction of the symphysis approaches the horizontal, the sacrum is very highly curved and the excavation is roomy, the false pelvis is broad with a wide transverse flare, the acetabula are almost directly under the body weight or may be behind it, and the line of pressure of the body weight is consequently almost directly across the axis of the inlet. The inlet is of normal shape, but flat rather than

round. The whole spine is of mechanical necessity marked by very highly developed curves, the lumbar curve and the longitudinal curve of the sacrum being especially marked. The hips are wide in appearance, the legs are knock-kneed and often somewhat bandy-legged. The figure as a whole is markedly, if not excessively, of the feminine type, and these women usually have an active sexual life.

This pelvis tends intrinsically to be roomy and is then not of operative importance, but the great inclination of its brim makes a difficulty in labor even with normal diameters, and a very serious obstacle whenever its size is even slightly diminished.[1] When a pelvis of this shape is small in comparison with the head, natural labor usually fails and the intrapelvic methods of artificial extraction have an exceedingly high fetal mortality. The use of forceps high is made difficult, and frequently ineffective, by the posterior position and the excessively backward traction which is necessary to extraction, and though version is a highly effective operation it is apt to result in stillbirth from the excessive strains upon the body and neck as the child is drawn around the nearly horizontal symphysis and through the highly curved pelvis.

In this pelvis the field for the intrapelvic operations is an exceedingly narrow one, and it should as a rule be subjected either to natural labor or the Cesarian section in accordance with its size. Its recognition in advance of labor and the estimation of its obstacle in connection with the amount of the other factors in labor is therefore of especial importance.

The probable existence of this pelvis may be suggested by the excessive antero-posterior curves of the woman's figure as she stands clothed, but a determination of the degree of alteration which is present necessitates a study of the spine in a standing posture after the corsets have been removed. The great curvature of the sacrum with the compensating excessive curvature of the lumbar spine, the deep intergluteal fold and the excessive inclination of the brim are readily appreciated in this position, but the internal palpation of the pelvis also furnishes evidence of the utmost value; the points of especial importance in determining the degree of alteration present being the length and direction of the inner wall of the symphysis, the angle between the superior and inferior straits, and the excess of curvature in the lumbo-sacral region.[2]

The obstacle likely to be afforded by the pelvis is then estimated by comparison of these points with the size of the conjugate as determined by measurement.

It is to be remembered in all cases that we have only one generally applicable measurement which gives us any direct information as to the actual size of the true pelvis, *i. e.*, the conjugate at the brim as calculated from the direct measurement of the diagonal conjugate. The other commonly taken measurements all relate to the false pelvis, and[3] are valuable rather as affording diagnostic information of the character of the deformity present than from the hint which they give us as to size.

The all-important and fundamental point is that every alteration in the shape of the pelvis has so all-important a relation to the rest of the skeleton in the ordinary mechanical efforts of locomotion, that there can be no alteration of its shape without correlated peculiarities of the spine, legs and feet, and in all the varieties of deformed pelvis observation of the degree of these correlated changes furnishes evidence of exceeding importance as to the degree of pelvic alteration.

It follows from all this that we are only in a position to estimate the amount of obstacle offered by the pelvis when we can postulate that we have a pelvis of such a shape, modified in this direction to such a degree, and likely to present an obstacle of large, moderate or small amount, because with such a degree of alteration of shape it combines a conjugate of such a size. This whole matter of the importance of the type of deformity present and also of the importance of estimating the degree of such alteration present in each case has but recently begun to attract attention as a matter of practical urgency, and we as yet lack exact methods for its study. We cannot teach it, we cannot put it within the reach of the general profession until we have established a normal standard, until we have learned the limits of normal variation, and have acquired methods of measuring exactly the degree of variation from the normal in each of the corollated peculiarities. For this it is necessary, first, to establish the normal by the measurement of large numbers of normal women, and, second, to go through the slow process of comparing a generally accepted normal standard with accumulated experience in abnormal cases. This means detailed work by many men, and its completion may take years or even a medical generation; until then scientific exactness is impossible. It is, however, in the meantime well within the powers of any experienced obstetrician to add greatly to his power of estimating the obstacle offered by a given pelvis, by training himself in observation along these lines. Only after such an estimation of the pelvic obstacle are we in a position to estimate its relation to labor, in connection with the estimated amount of the maternal muscular and nervous power, and the size and degree of ossificaton of the individual head.

The long established but, as I believe, incorrect, belief that it is safe to defer decision until after the failure of the maternal powers in labor has prevented any concerted effort to determine the extent to which we can estimate these powers beforehand, except by study of the history of past labors in multiparæ; but of late years a more careful study of the conditions of pregnancy has convinced some of us that such predictions can be

[1] The head of necessity enters the highly inclined brim in a posterior position, and the direction of the expulsive forces drives it against the outer side of its curved course, that is, much of the force of labor is wasted in driving the head against the symphysis.

[2] In marked cases the inlet of the pelvis may look almost directly forward and the upper portion of the posterior sacral region may pursue a nearly horisontal direction.

[3] Except in the Robert and similar pelves.

made with sufficient certainty to enable us to distinguish at least the more pronounced cases of obstetrical strength or weakness, with practical certainty. Lack of space and the fact that I have in two recently written papers [4] devoted myself more especially to the study of this factor in labor prevents my entering upon this subject at full length here, but some summary of it is necessary to any consideration of the indications for the primary performance of the section.

No new departure in medicine is likely to command confidence unless it accords both with the known theory of the subject and with the results of practical experience. It is therefore necessary to examine any such proposition from both sides; when a procedure is found sound in both ways it seldom fails of acceptance. Belief in this possibility of a prediction of the probable character of labor with success, in marked instances at least, rests on the theorem that the strains imposed upon the organism by pregnancy and labor are inherently similar.

The strains of pregnancy have long been studied and are well known. The development of the child, *i. e.*, the addition of its metabolism to that of the mother, and the consequent injection of an increased amount of waste products into her circulation throughout imposes an increased strain upon her eliminative system. The existence of the fetal circulation and the consequent increased pressure in the maternal vessels put an added load upon the heart throughout pregnancy. The increase of size and weight during the latter part of pregnancy involves an increased labor for the muscular and respiratory systems in the performance of all the ordinary efforts of life. The existence of all these added loads involves an additional expenditure in the nervous system which governs each and all of them. These several increased loads act and re-act upon each other. Whenever one part of the system fails under the load of pregnancy it increases the strain imposed upon the others, *e. g.*, when the maternal eliminative system fails to dispose of all the products of increased metabolism, the resulting toxemia in itself decreases the efficiency of the muscular system, and through the heart muscle the efficiency of circulation, which latter of itself impairs anew the efficiency of the eliminative organs, and so creates a vicious circle. The enumeration of the many forms in which deficiency of the one system affects the others must be omitted here, but will be apparent to all upon a little thought.

The strains of labor are these: the intense muscular activity of labor throws into the maternal circulation a sudden and considerable increase in the waste products of metabolism, and consequently involves an increased strain upon the activities of the eliminative system. The great increase in pressure in the uterine and general abdominal circulation involved in each contraction imposes an additional strain upon the heart. The nervous system is called upon to withstand the strains incident both to the maintenance of powerful muscular contractions and to the endurance of physical pain. These added strains, moreover, as before, react each upon the other, *e. g.*, any failure of elimination creates under physiological law a toxemia which decreases the power of muscular endurance and lessens the co-ordination of nervous control which is essential to effective expulsive efforts, etc.

The strains of pregnancy and labor are thus evidently similar in kind, and exerted upon the same organs. The capacity to endure strains so much greater than those of ordinary life is always dependent upon the normal existence within the individual of reserve strength with which to meet the occasional exigencies of life. We must recognize the factor of safety in vital existence as definitely as in bridge building. When an athlete is about to enter upon severe and long continued muscular efforts his factor of safety is carefully increased by the process known as training, *i. e.*, the organs which are to be exposed to strain are carefully developed by a process of gradual increase of the daily load. Under normal circumstances this is what happens to the organs of the woman during pregnancy. If her margin of safety is such that her heart and her muscular, nervous and eliminative systems maintain or increase their efficiency under the gradually increasing load of pregnancy, she may usually be depended upon for strong, sthenic labor. If her natural margin of safety is so narrow that these vital activities fail under the load of pregnancy, it is, to use the vernacular, "dollars to doughnuts" that they will fail more markedly during the added but similar strains of labor. These are the women whose labors are lingering, whose uterine contractions are painful but ineffective.[5]

These theoretical arguments appear to me to be sound. Are they supported by the results of observation? To answer this question each of us must appeal to his own experience, and I can only quote my own. I have been interested in this question for more than fifteen years, during the first ten of which I had under observation a mass of clinical material amounting at the end to about twenty-five hundred cases a year, and during the last five a consultation practice, which, though of course much smaller, has been prolific in cases of this kind. About five years ago, *i. e.*, after a ten years' interest in this question, I formulated for myself the theorem that the character of labor can be predicted from the character of pregnancy, and submitted it to continued observation. I watched it for five years longer before committing myself to it, but have now become convinced that in well marked cases, it is a safe guide in practice. I know that some other observers have reached somewhat similar conclusions and believe that as this problem becomes subjected to still wider observation this leading principle is likely to be generally accepted as trustworthy.

After estimating as carefully as possible the

[4] Jour. Am. Med. Asso., vol. xlix, no. 16, p. 1329. Surg. Gyn. and Obst., March, 1907, p. 306.

[5] These are the women who furnish the greater part of the mortality of labor plus the Cesarian section, *i. e.*, of the secondary and late section.

nature and degree of the mechanical obstacle offered by the pelvis, and the probable character of labor as predicted by the course of pregnancy, we have left for estimation the third factor in the result of labor, the size and degree of ossification of the head, a factor for the determination of which we have, in primiparæ, no other guide than physical examination during the last few weeks of pregnancy. We have no mechanically exact method of determining the size or degree of ossification of the head, but by repeated palpation of the child as a whole during the last weeks of pregnancy, aided by combined internal and external palpation of the head, and by forcing it firmly into the inlet by external pressure, I think we can gain an idea of its size and adaptation which, when combined with a full knowledge of the pelvis and probable maternal powers, will enable us to divide even primiparæ clearly into three classes: *A*. Cases which will undoubtedly be most safely delivered by primary Cesarian section. *B*. Cases which may be reasonably expected to deliver themselves by natural labor, and in which if natural labor fails the ordinary intrapelvic operations are not likely to present unusual difficulties. *C*. A large class of cases in which the decision is still doubtful.

In multiparæ this preliminary classification will be of course greatly assisted by the history of previous labors. It is a matter of universal experience that the labors of any individual woman ordinarily bear a close resemblance to each other, though the first labor is usually longer and harder than those which succeed it. If an accurate history of previous labors is obtainable, its consideration in connection with close study of the three mechanical factors, as already outlined, will usually make the decision easy. It may certainly be laid down as a safe rule that when an intrapelvic operation necessitated by alteration of the pelvic shape and diameters, has been so difficult as to yield a stillborn child at the hands of an experienced accoucheur, subsequent intrapelvic deliveries in the same woman are sure to be highly dangerous to the child, and are likely to be less favorable to the mother than the primary Cesarian section with its exceedingly low mortality and absence of subsequent morbidity.

For the doubtful class, whether primiparous or multiparous, a further examination is necessary. Either with the first pains of labor or at an appointed date, as the judgment of the attendant may dictate, such women should be shaved and both the vagina and abdomen prepared as for any surgical operation. They should be etherized and placed upon the table with abundance of light and assistance. The mechanical conditions presented by the pelvis should be re-estimated and the head examined both by bimanual estimation of its size and by pressing it forcibly into the brim with all the advantages offered by anesthesia and the absence of any hesitation about provoking labor. This further examination should narrow the doubtful class to but few cases, and in those few, if the operator wishes, the hand may be passed into the vagina and the fingers passed within the os between the uterus and membranes, thus subjecting the head to a still better bimanual examination of its shape and size, and permitting their use in estimating more exactly the adaptation between the pelvis and head when the latter is pressed strongly into the brim by external pressure from above. Palpation of the head with two fingers actually within the os at a height which enables them to play freely over the greater part of its surface affords a fairly accurate estimate of its size, and the examination of its adaptation to the pelvis, under ether, and under these conditions, gives very much more definite information than can be obtained at any earlier period.[6]

The single objection to this last method of examination lies in the possible risk of infecting the uterus which is inherent in it, but in the hands of a man competent to open the peritoneum through the vagina and under the same conditions of asepsis and assistance under which he would perform a vaginal hysterectomy, this risk seems insignificant, and is justified by the importance of the question at stake.

When finally the results of either of these last examinations into the adaptation between the head and pelvis are considered with reference to the obstacle offered by such an adaptation under the mechanism of the degree of deformity present, and in connection with the estimated muscular and vital condition of the patient as derived from her behavior during pregnancy, there should be but few cases left which cannot be relegated either to the ordinary care of labor or to an immediate Cesarian section; but for the cases which are placed under the ordinary care of labor (including the intrapelvic operations), the choice should be considered as final and irrevocable, *i. e.*, after they have been subjected to a full trial of the natural forces in labor, they should be treated by determined high forceps or version rather than subjected to the very considerable mortality of a late Cesarian section.[7]

In the very few doubtful cases which may still be left after the final examinations I believe that the choice should be made in accordance with the patient's vital adaptability to labor. Strong women, well equipped for labor, may always take their chances with the intrapelvic operations even with considerable mechanical obstacles; but upon the other hand it must be remembered that the ill equipment for labor which is shown by failure to withstand the strains of pregnancy is peculiarly an ill equipment for *labor*. Such obstetrically ill-equipped subjects nevertheless withstand the ordinary surgical operations perfectly

[6] I have in the past in some doubtful cases applied forceps to the sides of the head and so drawn the head lightly into the brim by way of measuring its adaptation, and if tractions are carefully abstained from I believe this to be a justifiable process, but it is easily overdone. I have not found occasion to employ it for some years past, and I now consider the examination with the fingers within the os to be so far sufficient that upon consideration I am doubtful if I shall ever again employ the forceps in this way.

[7] Failures of selection may occasionally occur in this class and the choice of operation after the ordinary intrapelvic operations have failed should perhaps be considered here but is hardly within the scope of this article, other than to say that the very great maternal mortality of the section at this time seems to render it too severe an operation to be justified in the interests of the child alone. The choice in such cases would seem to lie between the operations of symphyseotomy, pubiotomy and perforation.

This table must not be interpreted as giving the full Caesarian lists of the operators quoted, since it excludes cases previous to the last ten years, and some cases in which the data were insufficient for quotation. It was intended that the table should cover cases of the classical Caesarian section only, but since this has been practically abandoned for late and neglected cases, it proved necessary to include the Porros there.

well, they do well under the primary Cesarian section, and for them in case of doubt the section should be chosen; these women in especial should never be subjected to the combination of labor and a peritoneal operation.

It may be objected to most of what I have said in this paper that such practice is beyond the powers of the general practitioner. I would respond, "It is undoubtedly so." This is not work for inexperienced men. It must always belong to those who are really obstetrical experts, and it is for them to bring about the conditions which permit such work.

Under the conditions of practice of but a few years ago the majority of cases of really difficult labor reached the hands of obstetric experts only after the failure of prolonged labor, and in hospital practice, and in some localities in private practice, this is still the rule. With such cases we must do the best we can. They are, however, not usually fit subjects for the Cesarian section. All results show that the late section, even when followed by a hysterectomy, is so fatal an operation as to be justifiable only for the absolute indication, or in those cases in which the mother's condition is so bad that the chances for the child take precedence.

This point is conceded by experts, but has been too little appreciated elsewhere. It is our duty to drive it into the comprehension of the general profession. The mortality of the late section is high when derived from the statistics of men who habitually operate early, but occasional operators rarely publish fatal cases, and if we could obtain complete statistics of all the operations done, I am sure that we should be appalled by the mortality of the late section.

A second and even more important practical point is, that we should teach the general practitioner that the time when his duty to his patient should lead him to seek the advice of a specialist is when he first feels anxiety about a pregnancy or an impending labor, and not after the prospects of both of his patients have been compromised by exhaustion in labor. In my own home, where the Cesarian section is perhaps looked upon with more favor than in any other locality in America, such consultations are steadily increasing in frequency, and especially among the better class of practitioners, and this should become the universal rule everywhere.

I think, too, that these signs of the times already show the possibility of a great improvement in the status of obstetrical practice in the future. The obstetrician of to-day is, as a rule, in the unfortunate position of competing with the general practitioner for the care of normal labor. I am far from underestimating the value of the best attendance in even normal cases, but we must not ignore the practical fact that there are now great numbers of men who can furnish a class of attendance on normal labor, and on ordinary

operative labor, which is so nearly that of the expert as to satisfy the community. Most such men feel unwilling to decline the obstetric work which comes up among the families whom they attend for other troubles, and, however conscientious they may be, this fact renders it difficult for them to ask for consultations during pregnancy with specialists who are their competitors for the care of normal labor.

Once we can teach the great mass of the profession that real success in the management of difficult cases is only to be attained by foreseeing their difficulty, and that it is possible for sufficiently experienced men to select these difficult cases during pregnancy; once we can teach them that in such cases the ordinary, reckless and careless habit of trusting to nature, *i. e.*, to blind luck in labor, and of sending for a specialist only after the mischief is done merely leads to ill health to the mother and death to the baby, — we shall find all the better class of general practitioners willing and glad to consult beforehand men who have especial knowledge, and who do not attend normal labor.

It this proves to be the future of obstetrics it cannot be doubted that obstetricians who are not at every one's beck and call for normal labor, but who find their practice in the management of really difficult cases alone will be in a far more enviable position than that occupied by most obstetric experts of to-day.

THE ORIGIN OF RIGHT-HANDEDNESS.

BY GEORGE M. GOULD, M.D.

Deprived for a time of the use of his right hand, Carlyle was struck both by the vast importance and the mystery of right-handedness. He forthwith pronounced the question of its origin as one "not to be settled and not worth asking except as a kind of a riddle." He was more correct in saying that right-handedness is "the very oldest human institution that exists, indispensable to all human co-operation whatsoever; no human cosmos possible to be ever begun without it." Since the entry in Carlyle's diary was made hundreds have despaired or failed in the same manner to see any possible solution of the "riddle," and all the time, to an extent which Carlyle could never have dreamed, the extension of the influence of right-handedness has penetrated more profoundly and dominatingly into all the departments of practical, commercial, manufacturing and social life. There is no medical science or practice which can ignore it; the law must take constant cognizance of it; mechanics and tool-making are dominated by it; in every evolution or drill of ships or soldiers it is obeyed and kept in mind; and to railroads it dictates wrecks and millions of dollars of expense or savings. It makes or mars the calling, or failure, the success, happiness, or suffering of far more persons than is usually suspected, and scarcely one of us is unaffected in some way for good or ill by our dextral or sinistral complications, co-ordinations and inco-ordinations. There are at least two million left-handed persons in our country, and they are either excluded or handicapped in almost every occupation they may adopt.

But Carlyle's insoluble "riddle" and the perplexities of hundreds of writers is now easily cleared up. The origin of right-handedness and left-handedness is plain, and equally so the history of the puzzle of "the Rule of the Road." Barbaric custom and war are the source of right-handedness; medicine, including cerebral anatomy and physiology, is able to explain the development of general right-handedness upon which rest all the mysteries of the Rule of the Road.

Beyond question the beginnings of right-handedness, and of general right-sidedness, date historicly to primitive war and barter and the tally stick. The first differentiation of function in the use of the hands doubtless arose in telling off the left hand and arm to hold the shield which should protect the heart side of the body from the adversary's blows. This hand thus became known as the shield-hand. Except in a few very modern tasks the fact has dictated that the left hand has been generally the holding hand, chosen instinctively for the more passive or holding tasks, those requiring the less delicate or expert proficiency. Custom and language have long crystallized into an acceptance of the usage and even gone so far as to call the unlucky and misfortunate and awkward by the words *left, sinister, sinistral, gauche*, etc. Conversely, the right hand was chosen for the positive fighting task, and called the spear hand, and some of the most prized virtues, dexterity, dextrousness, etc., were named after the cultivated abilities of the right hand. The oldest Greek vases, and Homer, even the cave-men, demonstrate the existence of the distinctions of shield hand, spear hand, and of right-handedness generally. In Xenophon's "Anabasis" the usages had become the routine of all military drill and discipline. In Smith's "Dictionary of Greek and Roman Antiquities" under the caption "Exercitus," may be found illustrations of the distinction emphasized. For instance:

> "The facing to the right was always the usage, because if the evolution were performed in the face of an enemy, the shielded side could be presented toward him. . . . Similar maneuvers took place if the enemy appeared on the left, though, as this was the shielded side of the soldiers, and the danger was consequently less, it was frequently thought sufficient to keep the enemy in check by means of the cavalry and light troops. One point that a general had to be on his guard against was the tendency of an enemy, when advancing ἐπὶ φάλαγγος, to sheer off towards the right, each man pressing closer to his right-hand neighbor in order to protect his unshielded side, so that the right wing frequently got beyond the left wing of the enemy."

The Roman army *exercitus* fixed the working of right-hand and left-hand orders down to the most minute details, and at West Point to-day the thousand peculiarities of military drill and custom, and command are exemplifications of the

consequences of shield hand and spear hand. Xenophon is still in command of every army in the world. Within the memory of living men companies of American militia often had, at the end, tail, or left of the battalion, a left-handed soldier, placed there in order that his musket, carried in his left instead of his right hand, might not clash with the right hand and its held gun of his next, right-handed, fellow.

In the word *digit*, and in the Roman numerals, and in the five strokes or cuts of the tally stick, we have the most abundant and abiding testimony as to the origin of right-handedness and the location of the speech center, writing center, and counting center in the left half-brain. Counting, writing and speaking are single functions united into act by the volition, the seal and ratification of willing. By all savages for all time, in bargaining, the right hand has been held aloft, and one, two, three or four fingers shown and flung at the opposed bargainer. The gesture is always that of throwing the fingers or numbers at him. The whole hand is flung more energetically, when five is intended, *i. e.*, the letter V of the fork of the thumb and first digit. The scratches on the tally stick tell the same story and the diagonal thumb line, denoting *five*, run across four digits from upper left to lower right hand corner, indicates the thumb or fifth number. And so on, to *ten* or *X*, the crossed or doubled thumbs and to all other numbers. A close study of the Chinese and Japanese numerals convinces that the Roman system described, ancient as it is, is but a late offshoot of far older oriental usage, in general features the same the world over, and ages before history began.

The significance of these illustrations of primitive and persisting sign language, gesture language and counting language is that as they are executed by the right fingers and right hand, the motions of these fingers and this hand are instituted and innervated by " a center " or collection of brain cells in a certain spot (called Broca's convolution) placed in the left side of the brain. With one finger held up, or more, or the whole hand, with one or more cuts in the tally stick made, there was (and as the schoolboy's lip-motion in learning to read demonstrates) the spoken word, one, two, three, etc. Speech is almost the sole and surely the chief muscular function that is single, not double, and which must be executed from a single initiating center of power and control. It is the fusion of all bilateralism, of all bodily and mental components and diversities into the unitized resolve which the whole body, mind and future, must obey. For the right-handed man this center of nervous origin and control is not in the right half-brain, nor in both half-brains, but only in the left. There also are the nervous or ganglionic mechanisms of memory, of writing, of the expert vision, of hearing, of leg-and-foot motion, which may be or are necessarily bound up with the right-hand deeds, the laryngeal and vocal acts issuing in language, or resolve, or social determination. The two halves of the brain are remarkably independent and separated from each other, as a thousand facts of physiology, disease and injury to brain-substance show. Therefore an injury to the speech or writing centers or to the centers of motion of the right-hand fingers of a right-handed person at once paralyzes or destroys, partly or wholly, the power of speech, of writing, of memory, the significance of words, etc. A similar injury to or disease of the corresponding parts of the right brain has no effect whatever upon these functions and acts. The child is born with no discoverable differences of cerebral structure or substance of the two cerebral hemispheres, and none ever appears thereafter. But about the sixth month of life the babe, which will naturally become a right-handed one, begins to put forth the right hand instead of the left to grasp an object, and the cerebral matter about the left third frontal convolution, however unchanged or like that on the right side, is thenceforth increasingly and exclusively used to control the organs of speech, of writing and of memory. Just here comes into view the overlooked fact that the degree of right-handedness, of general dextrality and even of vocal and mnemonic function is different in different persons, and also that it is all a question of growth and progressive development. In the grunting savage or peasant the speech center, although located in the left brain, must be tremendously more simple than in a musician who knows by heart and sings and plays a thousand pieces of music, who speaks and writes a dozen languages, etc. The differentiation and complication of the cerebral mechanism whence spring all the acts begins in infancy with simple homogeneity, and grows in complexity with every year of added life. With each added year of differentiation the expertness grows, and it grows because the single cerebral mechanism has become more and more complex. Therefore with each added year the impossibility of educating the corresponding centers on the right-brain becomes greater. The ambidextery sillies must therefore begin with infants if they are to succeed in making a dextral child of one naturally sinistral. Moreover, historicly, the trend in all human beings is for them to become more and more exclusively and despotically either right-handed or left-handed, so that with each added generation the impossibility of ambidexterity will increase. Even now the attempt to reverse the law as existing in school children is both useless, expensive of life and in reality impossible. No attempt can wholly succeed; none should, and the partial successes produce cripples and awkwards, if not disease and tragedy. The most foolish, impertinent, ignorant, expensive, resultless and maiming fad is that of the ambidexterity mongers. They do not know what they want, do not know that they cannot succeed, do not know that they curse the victim of any partial success. In infancy the left-handed child may be trained to be a right-handed one, but never to be an ambidextrous one. Why should a violinist bow equally well with both hands, and finger equally well with both hands? Why should he write equally expertly with each hand?

The fatuity becomes amazing with the recognition of the fact that right-handedness is necessarily bound up with right-eyedness, with right-earedness, with right-footedness. To train the child to be ambidextrous, eyes, ears and feet, — all must be trained to equal expertness in all tasks, and this is ludicrously impossible. We are as much right-eyed as we are right-handed, as any one can prove by looking at the image of the finger or a pencil held upright a foot before the eyes. Alternate opening and closing of each eye demonstrates (with some exceptions understood by oculists) that the right eye is unconsciously the one chosen to " fix " the image.

The reason for this general choice of the arm and hand, of eye, of ear and of leg and foot for conjoined expert tasks is easily recognized. It insures a speedier and more accurate synthesis of the cerebral functions which must be co-ordinated into a single act and result. The independence of the two halves of the brain makes it necessary that the bodily organs most commonly acting together and most interdependent should be incited and controlled by the cerebral centers in close contiguity and in one side of the brain. There is a measureable slowness of nerve-current transmission (between 100 and 200 feet per second), and even if the connecting links (" commissural fibers ") between the two brain halves were much more intimate and numerous and short than they are, rapidity and accuracy of correlation and unification in willed act would be impaired; and the safety and decision of the entire organism imperiled, if one or two of the coacting centers were in opposite hemispheres. That in the right-handed all these centers of origination and control are in the left, and in the left-handed in the right half-brain, is an inevitable consequence of the location of the speech center and writing center exclusively in one or the other. Writing and speaking are closely interdependent, both in origin (gesture, sign language, counting, Roman numeral or digit-throwing), and in all subsequent history and evolution. Their centers of origin and control must therefore be in close neighborhood and intimate union. Vision which preceded and accompanies all must therefore be in the same side of the brain. This, of course, holds as to hearing and, although less differentiated, to the associated leg and foot movements.

An astonishing and interesting consequence of all this almost draws itself. It becomes plain that, in the right-handed, intellectual life and progress are by means of the mechanisms of the left cerebral hemisphere. There is no intellect as we understand it except through speech, vocal and written, and the instruments of this function exist only in the left brain of the right-handed, and in the right brain of the left-handed. Mentality of the dextral therefore lives preponderatingly in and through the left half-brain. The fact strongly emphasizes and capitally illustrates the great biologic law that all progress consists in differentiation of function. In the evolution of civilization each bit of cortical brain substance is being told off to a certain peculiar office. That large parts are still without particular and discoverable duties argues plainly for the great progress and differentiation of function in the future of humanity's advance. The areas of the more unused half-brain (the right in the right-handed, the left in the left-handed) occupied by the speech and writing centers in the more active half, show microscopically no failure or weakness of part or mechanism. If they did heredity would long since have eliminated the left-handed, and the right half-brain would become changed and atrophied except in those parts originating the muscular activity of the right side of the body. Possibly, the recurrence itself of the two or more per cent of left-handed persons prevents the atrophic tendency in the right-handed. Left-handedness is therefore probably not decreasing, and the forming organisms of the infant may become left-handed, etc., with no want of perfection in any part. The emergency finds the inherited mechanism ready for its task.

In this light and by reason of these facts one sees that materialism is absolutely disallowed. The speech and writing mechanisms of the brain do not as such exist, even functionally, in the fetus or newborn child. They are creations, slow creations, during childhood and youth. At any time they are instruments and mechanisms, expertly manufactured by something not themselves, used as a piano-key and string, and as all the keys and strings, as the piano itself, by something that plays upon them just as a pianist plays upon his instrument. That the instrument can or does make itself, that the player and piano are indistinguishable and of one substance, are the most unwarranted of pseudophilosophic assumptions. Far better than either philosophy or religion, physiology thus demonstrates the existence of the life and spirit of man, apart from the material of his body and its mechanisms.

There is much obscurity and misconception as to what really is the nature and fact of right-handedness, right-eyedness, etc. The crudest blunders, for instance, exist even in learned monographs as to right-footedness. In dressing, a dextral man begins by first putting his left foot in the left trousers-leg; he places his left foot upon the spade or shovel; he jumps from the right foot; kicks with the left; the boxer and prize-fighter places the left foot and arm forward; the rider vaults a horse from the near side, and with the left foot in the stirrup first;[1] the entered apprentice mason " steps off with the left foot first "; all soldiers, since time began, start the march by first advancing the left foot. All of these things are conclusive proofs of right-footedness, and not of left-footedness, as many claim. The right foot and leg are unconsciously chosen as the strongest, the most steady, best co-ordinated, most expert ones, with which the spring, the determining or force-giving factor, is made. It is of course nonsense that animals are right-footed or left-

[1] In the *Art of Horsemanship* Xenophon gives the most detailed instruction as to the method of mounting the horse, after which he says, " I think it good that the horseman should practice springing up from the off-side as well, on the chance that he may happen to be leading his horse with his left hand, and holding his spear in his right," etc.

footed. The differentiation could only arise with sign language and counting, and animals do not make gestures or count. No doubt that right-footedness in man is not so far advanced as right-eyedness and right-handedness; there are more exceptions, less differentiation of function, etc., but it is essentially present, and in process of evolution.

Right-eyedness is also subject to more exceptions than right-handedness because of the peculiar liability of the right eye to be thrown out of its function as the "dominant" one, or leader, by many ocular diseases, by injuries from blows, and especially by a more disabling optical defect (astigmatism, hyperopia, etc.). The struggle of nature to preserve the dominant function of the right eye is patent in the case of nearly every patient that comes into the oculist's office. The right will preserve its acuteness even under a greater optical defect than that of its fellow; the left is the one more frequently diseased and lost, and even with lessened visual sharpness the right is often retained as the dextral one. For there is tragedy when from any cause the right-eyed man in adult life is made into a left-eyed patient. Every act and co-ordination and judgment becomes slower, more awkward, more difficult and more inexact in result, because the visual factor in every act (and even every thought) is furnished by the opposite far-away and more inexpert center. There are few greater afflictions than one I now am witness of — paralysis of the upper lid of the right eye in a right-eyed person occurring in full adult or late life. The most amazing consequence of right-eyedness is lateral curvature of the spine. Approximately about 20,000,000 of the people of the United States have lateral curvature of the spine, and of these about three fourths, or about 15,000,000, indirectly owe their disease to right-eyedness. The deforming and crippling writing position which causes the deformity of the 15,000,000, is due to the necessity of bending the body and head to the left in order that the right-eye may see the pen point. The right eye must see the intellectual thing written even though the distortion of the back and tragedy of a life result!

When a right-handed person is made into a left-handed one by a broken arm, or by the equal misfortune of a foolish parent wiser than nature, the results are almost sure to be baneful. If undertaken early enough in youth, the foolishness of trying to train the right hand by whipping, tying up the left, etc., may sometimes succeed, but at the expense of a life of trial, handicap, or even wretchedness and disease. Ill success in life is often caused by this folly. It is chiefly the writing act that arouses the sorry parent and the ambidexterity-crank to their impertinent opposition. But it is precisely the writing act which locates the speech center in the side of the brain opposite the writing hand. Writing, bound up with speech and memory, is the demonstrated origin of the localization of the speech center. Science, disease, physiology, tumors of the brain, etc., have proved that one may be left-handed in everything except writing, and that the speech center is in the left half-brain. I have a patient who, as a boy, was cruelly compelled to stop writing with his left hand, and after years of torment he was made a dextral writer. And for forty years he has never been able to think and write at the same time. He cannot write the simplest letter that requires thought, planning or judgment. He sends miles or waits hours for a stenographer, and can dictate the most technical engineering plans with clearness and rapidity. Another patient has been made mentally morbid, and a life of invalidism has resulted from the same cause. In the United States there about are two million originally or persisting left-handed persons, a portion of whom are mental and even physical cripples from the injudicious antipathy of parents or teachers to the "south-pawed." In comparatively few cases is the attempted change entirely successful. They have a sufficiently hard time to get left-handed work benches, tools, etc., and to pursue the avocations of the right-handed, without doubling their handicap by dividing the centers required in a composite act between the two dissociate brain-halves. How pitiable is the lot of the left-handed soldier! I have two thorough-going left-handed patients who by training have learned to shoot a rifle from the right shoulder, but they depress the right eye below the gunstock and awkwardly sight with the left eye! When all his sinistral functions are performed by the left-handed man by means of the cerebral centers located in the right brain hemispheres he is as efficient, quick, intellectual, etc., as the right-handed person. The Jewish left-handed slingers, it is said, could cut a hair set up as a target. Because there are a few persons with the heart on the right side of the chest it would seem to be even more the duty of the ambidexterity societies and of officious parents to remove it to the left side by surgical operation! Let the left-handed child alone! Nature is quite as wise as the ignorant intermeddlers. For ages the stranger, the unknown and unusual person has been looked upon with dislike, and has even been persecuted because he differed from the one without other excellencies than that of being like his neighbors, or like the majority of them. The dislike of left-handedness is a relic of the same vicious egotism. The left-handed person is stupidly charged with being "sinister" and unlucky, and all because ages ago to the left or shield hand was given the natural task of protecting the heart and life of its master!

And a little quiet and unprejudiced observation would have shown that it is rather a division of tasks, a happy and advisable differentiation — not subordination — of function, that is coming about in the jobs which the left hand is commissioned to do. In the sterling old tasks of shoveling, pitchforking, chopping with the ax, etc., the left hand almost divides the honors equally with the right. In locomotive-engineer driving, it is indeed the left hand that is on the throttle valve. Especially in the musician's art both hands must be equally expert and active. The fingering of

the left hand of the violinist is technically as fine and dextrous a task as the bowing of the dextral hand. It is of vast significance that all tasks should be divided up and allotted to each hand, each eye and foot (perhaps to each ear?)— all except the one of intellect bound up with writing, speech and memory, which, necessarily single, must be shocked into action by a single and not a duplicated set of organs, which are placed only in one cerebral hemisphere. It is of no advantage to be able to eat with the knife or fork with each hand alternately and equally well; it is a positive disadvantage. Should every musician have two pianos, one as now constructed and another with the bass keys on the right, and should he learn to play equally well upon each piano? That is what ambidexterity means. The poor left-handed person is already almost entirely shut out from any musical calling, except that of singing, and there are many other avocations in which he is handicapped or doomed to failure. From this point of view one may wonder if the number of the left-handed will not decrease in the struggle for existence in civilization's progress of the future. There are no statistics to help us decide the question. The exclusion of such unfit ones will at least be only hastened by any interference with nature's production of left-handedness. With a very few years in childhood of nascent right-handedness or left-handedness started, the habit becomes so fixed that years of punishment, derision, strapping up the left hand and other methods of torture are utterly powerless to alter the developing and educating speech center in the right brain.

The bleatings, mooings, bellowings, roarings, etc., of vertebrate animals, together with the cries of the infant during its first months of life, are not language, or even the beginnings of language. Whether they express or are understood to express desire, pain, anger or passion, they are the voice, or suggestion of the voice, of the organism as a whole, undifferentiate, non-intellectual, — the cry of the abstract physiologic machine, wanting or pained, and as a unit; they are not inspired or guided by vision or by definite motived act. The air issues from the caverns of appetite and emotion, and in passing through the upper organs of respiration is slightly transformed into inarticulate sound. The vegetal or automatic organism is its origin and end. If innervated by the cortical centers these cries probably spring from a bilateral origin. Only when they become purposive in the slightest degree, when the other senses, and especially sight, are called in to furnish data and help for the motived and designed act, does the innervation of phonation arise in a single or one-sided center; the continuous evolution of the speech center thus becomes established and progressive. The "precise" but indefinite time at which this monolaterality begins is the "precise" but indefinite time when inarticulation becomes articulation. Articulate phonation is the intermediate of specialized and designed acts; it is the voice of intellect, choice and purpose. It is compositely formed out of the factors of sight, feeling, hearing, etc., furnished by individual, topographically placed, and neighboring cerebral centers. In a certain individual right-eyedness is doubtless the determining factor in localizing the developing speech-center in the left half-brain. The individual misfortune, possibly tragedy, comes from a compelled change of plan after the localization on one side is under way, or established. A higher error of refraction in the right eye, or the results of disease, such as keratitis, conjunctivitis, squint, etc., may bring about the misfortune. To produce left-eyedness, when obviable, by reckless operations is, in the surgeon, a scientific blunder. To will and compel right-handedness in the naturally left-handed is a crime.

Physiologically, therefore, the reason why an infant puts forth the right hand to grasp objects is because the right eye is the one which is nearest perfect visually, anatomically, or opticly. The law derived from the phylum of the entire past is that the right eye and right fore-foot, or right hand, must work together. In all animals the right eye governs the placing and action of the right front foot of the right side of the body, the guarding against dangers on the right side, etc. The left eye has the same office for the left side. Heredity has place in the creation of the more nearly perfect right eye. If the left eye of the infant is the better seeing eye it will grasp at objects with the left hand, and become left-handed. Handedness, if one may devise the word, becomes either right-handedness or left-handedness, according to the dictating condition of the better eyedness, right or left.

MEDICAL EXPERT TESTIMONY.*

BY E. W. TAYLOR, M.D., BOSTON.

THE subject upon which your secretary has asked me to speak has been much discussed from various points of view. It must, however, remain of interest until some more satisfactory system of expert testimony is devised than that at present in vogue. The existing method is admittedly unsatisfactory from the medical standpoint. Each great trial which excites much public interest is a clear indication of this fact. It is sufficiently evident that the medical man is placed at a disadvantage by present methods. Is there a remedy? So far as I have been able to observe, the legal profession as a whole thinks not. From time to time a vigorous agitation takes place, articles are written, propositions are made and nothing results. Some years ago in Boston the matter was seriously taken up, both by physicians and lawyers, but beyond various expressions of opinion no positive reform was instituted. Whatever the attitude of the law may be, physicians remain dissatisfied and are busily searching for methods of procedure which will not conflict with the rights of the people, but which will

* Read before the Worcester District Medical Society, Sept. 11, 1907.

place the medical profession in a more dignified position.[1]

In the first place, what are some of the difficulties of the present situation and how far are the charges against the medical expert witness justified? In what follows I shall attempt to approach the subject from the standpoint, first, of the court, secondly, of the jury, thirdly, of the attorneys for prosecution and defence, and, finally, from that of the medical expert witnesses appearing for the plaintiff and the defendant. It is clear that each of these elements in the modern jury trial looks upon the point at issue from a different angle.

I. The presiding justice maintains an absolutely unbiased attitude toward the litigation over which he is presiding. His estimate of the witness, whether or not such witness be classed as an expert, is based solely on the honesty, clearness of statement and knowledge of his subject which the witness shows. Quick to see the wavering of a prejudiced witness and the floundering of an ignorant one, to discover his honesty or prejudice, and to recognize straightforwardness, the judge naturally represents the intelligence of the situation, not only in points of law but also in the estimation of character.

II. The jury, men untrained in the law and also in medicine, stand as the final arbiters of the veracity, knowledge and credibility of the medical expert witness as of the ordinary witness. To make this even remotely possible the witness is cautioned to speak in commonplace language and to avoid even the semblance of technicality, however difficult of accomplishment this may be. He is continually being told, with varying degrees of severity by the attorneys and by the court, that he must simplify his language, that he must state facts and elucidate theories, however subtle and surrounded by obscurity they may be, in the language of the street. Conceive the futility of explaining the phenomena of hysteria or of the neuroses or psychoses to untrained and often ignorant men without using the terms which have grown up about and form an essential part of the subject. The situation is an impossible one. What happens? The expert doesn't explain. He leaves often a wholly wrong impression. He finds himself incapable of expressing his real opinion, what with the badgering of the lawyers and the restrictions put upon him by the court. Occasions will occur to many of you in which you have left a false impression because of this limitation of your means of expression. I remember on one occasion being called to account for the use of so commonplace a word as "exacerbation." Again I recall a long and fruitless discussion between the cross-examining attorney and myself on the use of the word "neurosis," which the attorney insisted upon defining, apparently to suit his ends, in a wholly inaccurate way, to which I was unable to agree. Under ordinary conditions much of the medical expert testimony is wholly meaningless, and the verdict is determined by the saving grace of ordinary common sense.

III. The attitude of the attorneys, whether for the prosecution or the defence, in relation to the medical expert witness is quite different. The attorney's object is to win his case by the use of all legitimate methods as allowed by the presiding judge. He regards the witness as legitimate prey, whether for or against him. His aim naturally is to bring out the points which favor his contention and to minimize to the last degree the other side of the question. To this end he resorts to methods which place the expert witness wholly at a disadvantage in that he is obliged in answer to the questions asked to exaggerate one aspect of the case, however desirous he may be to express the whole truth as he sees it. From a legal standpoint this is fair and essential to the system of expert testimony as at present constituted. The cross examination is designed to overcome this tendency to apparent bias, and it is apparently the cross examination which renders expert testimony so difficult and irksome to the ordinary physician. Every effort is made by the cross-examining attorney to disclose inconsistencies and to confuse the witness. If the witness can be placed in an absurd position, he may be summarily dropped without further effort to get at his real opinions, naturally leaving a wholly false impression on the untutored minds of the jurymen and placing the witness in the humiliating position which his knowledge by no means justifies. Again the physician finds himself the victim of a system which denies him the privilege of free speech, under circumstances which may demand all his calmness and acumen. A distinguished physician once told me that he would not again testify unless he be allowed to state both sides of the question to the jury in his own language. From the standpoint of the attorneys, therefore, the witness is "used," as the legal expression is, to subserve the ends of their client regardless of the whole truth of the situation. The expert witness leaves the stand, in the great majority of cases, without having given his complete and unbiased opinion upon the question at issue. It is at best a garbled statement. This is consistent with the purpose of the attorney, whether he appears for the prosecution or for the defence. The skill and success of the trial lawyer depends in large measure upon his method of handling witnesses, and his capacity to draw from them those facts which strengthen the contention which he is defending. The physician is something of a puppet in the hands of the skilled attorney. He certainly does not stand in the independent position in relation to the issue at stake which he maintains in other professional capacities.

We are told that the distortion of statement which an attorney is usually able to draw from a witness is neutralized by the system of cross examination, and that the outcome of the state-

[1] In this connection two papers by Prof. Hugo Münsterberg which have appeared in the September and October numbers of *McClure's Magazine*, are of interest, entitled, respectively, "Nothing but the Truth," and "The Third Degree."

ments of a medical witness is thereby sifted down to fact as would be possible by no other method. This I strongly doubt. Lawyers vary widely in their capacity to cross examine, as do physicians in their capacity to answer questions put with hostile motive. The attorney who sneers at a witness, who attempts to confuse him by tricks of expression, who makes him ridiculous, who minimizes the main issue by an insistence on irrelevant details, who abuses him without reason, is well known to all of us. Worse than all this is the direct examination conducted by an attorney who is wholly ignorant of the subject about which he is asking questions. One of the most annoying positions in which an expert witness can be placed is to find no opportunity to state his case either on direct or re-direct examination because of the helpless floundering of his attorney. For these and similar reasons I do not believe in very many instances that the mature judgment of a conscientious medical witness is finally given to the jury under our present system, and the pitiable part of the situation is that each attorney is doing his best to prevent the clear presentation of such a mature judgment.[2]

IV. Leaving the discussion of the legal side of the matter, which possibly is somewhat out of our province, it will conduce to a clearer appreciation of the general subject to say something of the medical witness himself. First, the medical witness for the plaintiff: Few young practitioners who are working in special subjects, and particularly in the nervous system, fail of an opportunity to testify for the plaintiff in suits for damages which mainly fill our courts. The temptation is apparent. They are not overburdened with practice, they are glad of the experience of court procedure, they are promised liberal remuneration if the case is successful, while sharing with the lawyer the lack of money return in the event of an adverse verdict. Out of this general situation has arisen the pernicious practice of so-called contingent fees for medical expert testimony. The far-reaching evils of this almost universal practice are not fully appreciated. In the first place, it increases the number of suits for trifling injuries, because the lawyers know that men in good standing are easily to be found who will testify on a contingent basis. Secondly, it fosters the neuroses, and not infrequently, I believe, creates them by forcing through the ordeal of litigation many persons who would be spared were experts not so easily obtained. In the third place, the moment a physician places himself in a position where he has something to gain or lose by the outcome of a case he becomes in so far a partisan with all the consequences to his reputation which that implies. If all reputable physicians would refuse to testify for contingent fees, it would do away with much of the present unnecessary litigation and would be a distinct gain for the people as well as for the medical profession. The lawyers, many of them at least, are, for somewhat obvious reasons, in favor of the contingent fee. They urge their own risk in undertaking the prosecution of a case in which there is no financial backing, and I have even been a victim of the argument that purely from a charitable standpoint it was a duty to undertake cases on the basis of contingency. Time does not permit me to enter upon a discussion of the large question involved in this matter. It is sufficient for the present to express the firm conviction that the medical profession would be placed in a far better light and the litigants would be spared the development of many serious disorders, especially of a nervous character, if physicians for the plaintiff stood on the same basis of suitable reward for services rendered as do physicians who testify for the defence.

Leaving aside the question of fees, which after all is a subordinate matter, witnesses are too often regarded as allies of the attorneys, and at times, I fear, actually are. The medical witness, qualifying as an expert, is often young and inexperienced. He finds himself slipping from his supposed unbiased position, and magnifying or minimizing, as the case may be, the ills concerning which he is called upon to testify. He finds himself actually working with the attorney to bring about the discomfiture of his brother physicians who are appearing on the other side, thereby unconsciously adopting legal methods. He begins to be talked about among the lawyers as a plaintiff or a defendant man, and, rightly or wrongly, is looked upon by them, and also by his own profession, as a man whose opinion is preformed and whose testimony is known before it is expressed. There is no question that physicians are often misjudged in this matter, but do they not often expose themselves to this judgment? It must be clearly borne in mind that the legal and medical attitudes under the jury system are or should be different, and that as physicians we should guard against their ever becoming the same. We cannot be too careful in guarding against the subtle influences of gain, of prejudice, and of many conditions which under the present system tend to warp our judgment. It is wholly unfortunate that a medical expert should ever be regarded in the light of a plaintiff or a defendant witness. The present system, however, forces this distinction upon us. It is desirable that we do all in our power to minimize its evil effects.

The witness for the defence, which in the ordinary type of case is a corporation, is exposed to peculiar temptations. Here the very assurance of money return for services rendered carries with it a certain danger. If a man's mind is not quite settled on the significance of certain signs and

[2] In this connection a book by Francis L. Wellman, of the New York bar, entitled "The Art of Cross Examination," The Macmillan Company, 1904, will be found interesting, as showing the extraordinary methods resorted to by attorneys to gain their ends. The author says in one place, page 83: "The art of the cross examiner should be directed to bring out such scientific facts from the knowledge of the expert as will help his own case, and thus tend to destroy the weight of the opinion of the expert given against him"; and again, page 84, "No question should be put to an expert, which is in any way so broad as to give the expert an opportunity to expatiate upon his own views," etc. An examination of a physician, narrated on pages 94–97, is particularly illuminating, as demonstrating the impossible position in which a conscientious physican may be placed before a jury, through an unscrupulous method of cross examination. In this instance the attorney asked his questions in rhyme to the amusement of the jury and the discomfiture of the physician.

symptoms, which commonly appear in the person of the plaintiff, the influence is subtle but strong to mold his attitude toward the side of the defendant. His habit of mind changes. Plaintiffs come to be regarded as for the most part grossly self-seeking, if not absolute frauds. Corporations are long-suffering and abused. A certain lack of charity develops. Lawyers for the plaintiff no longer seek his services. All this is in one sense not blameworthy. His convictions may still be honest and his opinions well founded in reason. Nevertheless, the temptation cannot be overlooked and should not be minimized.

The natural result of the entire situation is that doctors are arrayed over against each other, as are lawyers. Partisanship almost involuntarily develops. The doctor assumes the legal attitude. He takes sides. He confers in the court room with his attorney to frame questions to confound his fellow practitioner on the witness stand, and the pitiable spectacle of medical expert testimony, which any great trial presents, is spread before us. The medical profession as represented by its experts becomes a laughing-stock. The jury disregards its statements. The press ridicules the so-called experts whose disagreements are emphasized to the last degree. Much time and money are spent in bringing out testimony so contradictory that the Court often actually instructs the jury to ignore it, and the whole farce of the present system is ingloriously exposed. We have recently seen an exhibition of this sort in a widely advertised New York trial which excited international comment and once again aroused the medical profession to the possibility of reform. The added misfortune is that precisely the same condition of affairs prevails in varying degree, depending upon the importance of the case and the emotions excited thereby, in all trials where medical witnesses appear on the two sides of the controversy. There is the same quibbling, the same tendency to cloak the main issue, in the small and apparently insignificant trial as in that to which the papers devote their most prominent space. The principle must remain the same while the present system exists.

Radical reform is at present unlikely. What can in the meantime be done quietly and unobtrusively by the medical profession? Each individual who testifies as an expert in court may at least further the cause of reform by the following means: refuse to be forced into even the appearance of partisanship. To this end refuse to testify on the contingent basis; decline to prompt lawyers in the court room; maintain an inflexible determination to state the whole truth as you see it, remembering that the emphasis on a single word or the tone of voice or manner may easily and very definitely indicate bias. Do not allow the natural disadvantage of your position as an answerer of questions to influence your temper or your judgment, and, above all else, do not permit yourself to fall into the common error of testifying regarding matters of which you are ignorant.

In regard to this latter matter, it is evident that the points about which the greatest confusion exists in the court room are just those points about which the greatest confusion exists in the best minds of the profession. No definite final word has yet been said regarding the great problem underlying hysteria, the various insanities and the springs of conduct in general, and yet it is about these very facts that a medical witness is expected to state a dogmatic opinion, and too often is forced into doing so when his knowledge is as vague as the subject is vast. How many men, for example, who go on the witness stand and qualify as experts, are in the least capable of giving a succinct and clear statement of any theory of hysteria, an affection which plays so significant a rôle in many cases of litigation resulting from accident? How many men understand the significance of somnambulism, the manifold alterations of personality, on the subtle interaction between mind and body which occur in this protean neurosis? What justification have men whose lives have been devoted, let us say, to surgery, or departments of medicine remote from the nervous system, to express an opinion to the jury which in the eyes of the Court has equal weight with that of a person who has devoted his life to a study of these subtle questions? The whole matter is naturally involved in difficulties. Our knowledge at best is imperfect and often incapable of dogmatic statement, but the general plan of action is easily evolved from the chaos, and that is that no physician should testify as an expert in a matter before the Court on a subject in which he himself is not conscious of expert knowledge. The jury, the judge and the lawyers cannot be conscious of his qualifications as he is himself. For the furtherance of the best in expert testimony we must increasingly demand of ourselves that we will testify as experts only in those matters in which we have special knowledge.[3] A physician is or should be no longer called upon to give an expert surgical opinion in a court of law, nor should a surgeon regard himself as competent to give an opinion on some subtle matter relating, for example, to the nervous system under the cloak of a somewhat universal ignorance of the subject. We are not now speaking of that minority in the profession whose ignorance is notorious and whose continual appearance in court can be explained on no other basis than that of the desire for gain. This class of physicians, harmful as it is, is a somewhat negligible quantity. We refer rather to conscientious and in general well informed physicians who are disinclined to make sharp distinctions between ordinary and expert knowledge. We cannot expect the courts or the legal profession to help us materially in this

[3] The following position, for example, quoted in the *British Medical Journal* for Aug. 31, 1907, would be difficult to maintain under a rigid cross examination: "Dr. R. T. Williams gave evidence lately at Marylebone Police Court in a case in which a woman charged with being drunk and incapable denied the insinuation. Dr. Williams said that he found her in a 'mellow, comfortable state of drunkenness, recovering from irritation,' and in reply to an inquiry from the magistrate said that he distinguished practically seven stages of drunkenness: Irritable, mellow, pugnacious, affectionate, lachrymose, followed, if the total doses were large enough, by collapse and death. Mr. Plowden seemed much pleased with the classification, and said that it was a most instructive lesson of which his court stood much in need."

matter. It, therefore, becomes necessary that we should with increasing care scrutinize our own motives and diligently refuse to expose ourselves to the possibility of misinterpretation. To this end we must, as I have suggested above, testify only in those cases in which we are assured that our knowledge is such that we may legitimately qualify as experts.

Necessary as it is to do our utmost to elevate the character of expert testimony under the present conditions, efforts should not be spared to bring about a fairer relation between physicians and the courts in the future. Individual instances are multiplying in which to the satisfaction of all concerned commissions of experts have been appointed whose duty it is to report immediately to the Court. Many cases of the highest moment have been adjudicated on this basis during the past few years, and there is no question that many others will follow. By such an arrangement the physician appears at his best. He is selected after due deliberation by responsible and unprejudiced persons. He is allowed ample time for examinations, for mature deliberation on the results of his findings and for the preparation of his report. He is freed from the petty annoyances of an appearance in court, and from the possible disastrous expression of an opinion which he would not have made under other circumstances. The ideal toward which the medical profession must strive in this matter of medical expert testimony is that of an appointment by a central authority, of physicians to sit in judgment upon the medical aspects of the case presented. No doubt such a system, if universally adopted, would have certain objections and would possibly run counter to the general method of court procedure, as exemplified in trial by jury. The fact, however, remains that the present system is unsatisfactory as well to the legal as to the medical profession, and that the medical profession is placed in an invidious light thereby which it should strive by all legitimate means in its power to obviate and overcome.

Clinical Department.

TUBERCULOUS ULCER OF THE ILEUM. PERFORATION. GENERAL PERITONITIS. OPERATION. DEATH.

BY THOMAS F. LEEN, M.D., BOSTON,
Physician to the Carney Hospital,
AND
JOHN T. BOTTOMLEY, M.D., BOSTON,
Surgeon to the Carney Hospital.

A GENERAL peritonitis, resulting from the perforation of a tuberculous ulcer of the intestine, is sufficiently uncommon to warrant the publication of the following case. In proportion to the frequency of tuberculous intestinal ulcer, its perforation into the free peritoneal cavity may even be called rare rather than uncommon. The pathology of the affection would lead us to expect this. For the ulceration usually extends in a direction transverse to the long axis of the bowel. As far as the serous covering of the intestine is concerned the seat of the ulcer is commonly indicated by a local redness, a thickening and by the presence of small nodules; in other words, by a localized tuberculous inflammation of the peritoneum which favors the formation of adhesions between the affected locality and contiguous loops of intestine or between it and neighboring structures. It can readily be seen how this adhesion-formation, this agglutinating process, usually prevents the perforation of the ulcer into the free peritoneal cavity and favors the formation of a localized abscess, should perforation occur. Perforation of the lower rectum by a tuberculous ulcer is not uncommon, but with that fact we are not particularly concerned here.

The patient, an unmarried male of thirty-five, was seen by Dr. Leen in his private practice on the morning of May 18, 1907. For the past seven or eight years he has complained of a chronic cough with thick, yellow expectoration. In December, 1905, began a severe illness of three months' duration. The chief symptoms were dyspnea, ascites, edema of the legs, rapid emaciation and diarrhea with tenesmus. Recovery was slow and the illness was followed for some months by constipation which was rather intractable. Late in the spring of 1906, he had an attack of severe abdominal pain with vomiting but without symptoms of obstruction; he was confined to his bed for three days. Since then he has had five such attacks. For the past two years "bleeding piles" have been a source of great discomfort to him. Though his appetite has been poor, his weight has shown a gradual increase, his condition a constant betterment, and for the two weeks just previous to his final illness he considered himself perfectly well; his bowels were moving twice daily.

At 11 P.M., May 17, 1907, just as he arrived home from an all-day trip to Connecticut, he was seized with a dull abdominal pain, which made itself felt at first to the left of the umbilicus; it gradually worked over into the right lower quadrant, shooting down into the right testicle, but finally became pretty well localized in the left lower quadrant; it soon became severe and later agonizing; the patient felt feverish and was sleepless.

On the morning of the 18th Dr. Leen was called. The prone position of the patient, the flexed lower extremities and the anxious face plainly indicated suffering. The pulse, of small volume but fair tension, was 120; the temperature, 101.4° and the respiration, 18. The sclera of each eye was slightly icteric; the tongue was moist and coated and the heart, slightly enlarged to the left, showed a systolic murmur, mitral in origin. Examination of the lungs disclosed nothing abnormal. The moderately distended abdomen was very tender over a rather indefinite area of dullness in the left lower quadrant; the very lightest percussion there caused pain. Muscular spasm, though present over the whole anterior abdominal wall, was most marked over the tender area. The area of the liver dullness was slightly decreased; the spleen was not enlarged. By rectum there could be felt close to the left obturator foramen a tender, fixed, boggy mass of the size and shape of a Tangerine orange, halved in its long diameter. The urine had a specific gravity of 1,020, showed a slight trace of albumin and in the sediment were a few hyaline and granular casts. The patient's bowels had moved on the morning of the 17th but not since. Cathartics and enemata were used without avail. Surgical consultation was refused by the patient. By afternoon the distention had increased and the pulse had grown weaker; nausea was constant but there was

no vomiting. Dr. Sawin saw the patient in consultation with Dr. Leen. A provisional diagnosis of intestinal obstruction due to obturator hernia was made and immediate operation advised. The patient refused consent.

During the night of the 18th the patient's condition grew steadily worse; vomiting began; the pulse increased in rate and lost in strength. On the morning of the 19th the mass, previously felt by rectum, had disappeared and the whole pelvis seemed to be full of loaded intestines. With the hope that the obstruction had relieved itself cathartics were again tried but without avail. The patient failed rapidly, but it was not until 7 P.M. that he would consent to be removed to the Carney Hospital for operation.

He was then almost moribund. His temperature was 97°, his pulse 140 and his respirations were rapid and shallow. His face, covered with perspiration, showed the pinched, anxious expression of toxemia. His chest was negative. His abdomen showed general, symmetrical distention, general rigidity and tenderness; the latter was still most marked in the left lower quadrant where a mass could be indefinitely palpated. The whole lower abdomen was dull to percussion. Rectal examination was negative.

At the operation, done by Dr. Bottomley, a general peritonitis was found, due to a perforation of the ileum. The distance of the perforation from the ileo-cecal valve was not determined. It was about one fourth of an inch in diameter and was at the center of an indurated section of gut about three inches in length. The perforation was sutured into the partially closed operative wound in the abdominal wall. The pelvis was drained by tubes and wicks through two separate incisions. The patient was placed in the sitting position in bed and salt solution introduced into the rectum by the "seeping" method of Murphy. Death followed in about four hours.

After death the indurated section of gut was removed and sent to the Pathological Department of the Harvard Medical School. The pathological diagnosis was "Perforated tuberculous ulcer of the ileum."

Reports of Societies.

EIGHTH ANNUAL MEETING OF THE AMERICAN THERAPEUTIC SOCIETY.

HELD AT WASHINGTON, D. C., MAY 4, 6 AND 7, 1907.

THE address of welcome was delivered by Hon. HENRY B. F. MCFARLAND, president of the Board of Commissioners for the District of Columbia. DR. REYNOLD WEBB WILCOX, New York, responded for the visiting members.

Address by the president, DR. ROBERT REYBURN, Washington, D. C.

FIFTY YEARS IN THE PRACTICE OF MEDICINE.

After speaking of his early medical career, Dr. Reyburn describes the methods of treatment used in the period following the year of his graduation, 1856. Vaccination was performed by pulverizing vaccine crusts and inserting the moistened powder into the arm. The antiphlogistic method of treating inflammation was still in vogue, bleeding, blistering, purging. While no one would wish to revive bleeding after the old methods, yet he had seen cases in which prompt venesection had saved life. In eclampsia, threatened apoplexy and even acute pneumonia, he had seen prompt relief afforded in this way. The antiphlogistic method was followed by a reaction, and in 1860 and 1862, stimulants were given in inflammatory conditions. In 1862 Dr. Reyburn entered the Union Army, and from this point the paper deals largely with surgery. After describing surgical methods in vogue prior to the war, and contrasting them with those of the present day, he interestingly describes his army experiences. He contrasts the high mortality from gunshot wounds in the Civil War with the low mortality in the Spanish-American war. In the latter the universal use of first aid by antiseptic dressings did more than anything else to lessen the mortality. Also, the rifles used were more humane in that they carried a small bullet of high velocity, which penetrated the tissues more readily and caused less shattering than did those of the Civil War. The paper then deals with personal recollections of President Lincoln and of the scenes following his assassination. The address closes with an interesting account of the assassination, illness and death of President Garfield, Dr. Reyburn having been one of the physicians in attendance.

PURE DRUGS.

DR. HARVEY W. WILEY, Washington: After referring to the different classes of therapeutic agents, Dr. Wiley discusses the attempts that have been made to control the purity of drugs used as medicines. Such attempts have been made for many years. The United States Pharmacopeia, National Formulary and United States Dispensatory are efforts along this line. As early as 1848 a federal law was enacted governing the importation of adulterated and spurious medicines. Prior to this there had been established at the port of New York an examiner of drugs. His testimony before the Congressional Committee shows that the character of the drugs imported a half-century ago was far from satisfactory. At least one half of those which entered New York was adulterated or had deteriorated in value. Under the inspection of drugs their character has materially improved. Dr. Wiley was unable to say how far the new Food and Drugs Act will be applied to the inspection of drugs. The question is now before the Attorney-General for decision. If he adopts the common principle of construction, inspection by the Treasury Department will continue as before, with an additional inspection as required by the Act of June 30, 1906. It is probable that at least 20% of the drug trade will be affected by the provisions of the new law. This leaves about forty thousand articles of drugs to which the law does not apply except as to misbranding. He considers the subject of misbranding, the evils which attend the promiscuous sale of preparations of uncertain, unknown, or even questionable composition, and the beneficial effects which have followed proper and correct branding. Individuals who have not the most elementary knowledge of pharmacy or medicine are permitted, under the state and national law, to concoct almost any agent and sell it directly to the consumer. This is in marked contrast with the qualifications necessary for the practice of medicine and pharmacy. He suggests the following as the most effective method of control in this regard: that no one should be allowed to advertise or offer for sale to the public in any community any remedy of any kind who has not passed an examination before a medical examining board and received a license to dispense medicines and prescribe for patients in the locality mentioned. Thus, the patent medicine trade would be much restricted. After discussing the subject of standardization, the paper closes with an appeal to physicians to write original prescriptions rather than order the ready-made medicinal preparations.

DISCUSSION.

DR. REYNOLD WEBB WILCOX, New York, spoke of the standards set forth in the Pharmacopeia. Seven years ago he was appointed a member of the revision committee. The aim of the committee had always been to maintain the necessary efficiency and purity of drugs without making the standards so high that manufacturers could not come up to them. They were established after careful study and conferences with manufacturers. After the enactment of the new Pure Food and Drugs Act there came in a flood of protests from manufacturers, who claimed that they could not come up to certain of the standards. This necessitated a reconsideration of the subject, which resulted in revision of the standard in over four hundred instances. Never had the committee failed to lower the standard when it was conclusively shown that it was unreasonably high. He commended Dr. Wiley's work. The new law was a godsend to the physician, the pharmacist and the public.

DR. E. H. LONG, Buffalo, said that the profession could well rejoice that it had the aid of the government in the matter of drug control. He commended the suggestion by Dr. Wiley relating to a license requirement for those who wish to sell medicinal preparations. He commented upon the prevailing neglect of medical schools to furnish adequate instruction in the art of prescribing and the use of reliable and well-known remedies. Much could be done along this line to hasten the era of pure drugs.

DR. OLIVER T. OSBORNE, New Haven, said that now is the time to let the label tell. He related a recent experience at Hartford in an effort to get poison labels on bottles. There was much opposition from pharmacists and others, and finally two strenuous bills were brought before the legislature. Much to his satisfaction, however, the business men agreed at the preliminary hearing that they preferred the provisions of the new Food and Drugs Act. What can be done as to false and misleading advertisements? The Post-office Department must attend to this, as such advertisements are fraudulent and hence should be denied the use of the mails. He expressed regret that young physicians in the hospitals are prone to prescribe compounds which are kept upon the shelves ready-mixed for the sake of convenience. Thus they soon lose the ability to write their own prescriptions. After they leave the hospital they come into contact with the traveling salesman and his proprietary medicines. He made a plea for the writing of original and simple prescriptions.

DR. F. E. STEWART, East Orange, commended Dr. Wiley's work. The medical profession and the public could not be too grateful for governmental aid. He commended Dr. Wiley's suggestion as to license requirement. Dr. Gould had said that any one can practice medicine without a license except a physician or a pharmacist.

DR. L. F. KEBLER, Washington, related interesting instances in which articles which were misbranded or falsely advertised were brought to the attention of the post-office authorities with the object of having them excluded from the mails. In many instances failure was due to the difference of opinion among the medical witnesses as to the efficacy of the "cure" under consideration. He testified as to the dense ignorance of many of the promoters of these "cures" and cited instances in illustration.

DR. WILEY, in closing, said that the Post-office Department had accomplished all that it could under the law. He had always received from it sympathy and help in his work.

SOME CRITICISMS OF THE UNITED STATES PHARMACOPEIA.

DR. REYNOLD WEBB WILCOX, New York: Dr. Wilcox answers some of the criticisms that have appeared since the last revision became official in 1905:

1. "Many agents have been retained that are not in general use, while others much used have been omitted." As a matter of fact the changes were made only after the committee had consulted manufacturers, wholesale and retail druggists, and the members of the medical profession throughout the land. Every suggestion, no matter how humble its origin, was considered.

2. "More frequent revisions of the pharmacopeia are necessary." A greater frequency would not be possible, because time is needed for definite knowledge of medicinal substances. Active work for nearly five years was required for the present revision and this represents about the shortest time in which the work can be done.

3. "The time has come when the American Medical Association should take a hand in this work." Dr. Wilcox answers this criticism at some length, calling attention to the make-up of the revison committee. The medical profession is represented by 12 out of 26 members. The unfortunate showing which the Council on Pharmacy and Chemistry has made also demonstrates the utter unfitness of the American Medical Association to undertake the far more serious work of revision of the Pharmacopeia.

DISCUSSION.

DR. L. F. KEBLER, Washington, agreed with Dr. Wilcox as to the status of the United States Pharmacopeia. He knew of none equal to our own. It unquestionably has faults, but they will be remedied as fast as practicable. He could not see the justice of the criticisms mentioned in the paper. He expressed regret that Dr. Wilcox had so severely criticised the Council. It had already accomplished something, and for this it deserved credit. It could reach some things that the federal law could not. Already it had exposed a number of frauds; the members were working harmoniously together for a good end.

DR. F. E. STEWART, East Orange, also expressed regret that Dr. Wilcox had criticised the Council so severely. It was doing a good work and was attempting to solve some of the most difficult problems in existence.

DR. S. L. DAWES, Albany, referred to the nomenclature used in the Pharmacopeia. The names of remedies are in many instances too long and complex. They could be simplified to good advantage. Students who are taught long and complex names for drugs soon discard them after graduation for simpler terms. After graduation young physicians are apt to lapse from the high standards set for them in the medical schools. He thought this a valid criticism of the Pharmacopeia. Simplify the nomenclature.

DR. E. H. LONG, Buffalo, said that we should not take the position of condemning the Council. We should remember the short time that it has been in existence. Though young, it has already done some good. The Pharmacopeia, on the other hand, has been in existence since 1820. It can stand severe criticism. The more one comes into contact with the members of the revision committee, the more he sympathizes with them in their work. He was in favor of a simpler nomenclature.

DR. OLIVER T. OSBORNE, New Haven, said he hardly found his prescription blanks long enough for some of the terms he had to use. He suggested that accent marks be used in the next Pharmacopeia in order to

secure uniformity in pronunciation. He commended the work of the Council.

DR. WILCOX, in closing, said that perhaps his criticism of the Council had been rather too severe. Destructive criticism is not always advisable; constructive criticism is often productive of good. His was intended to be of the latter type. He fully appreciated the magnitude of the task before the Council. It had simply undertaken to do more than it could. He favored a simpler nomenclature, and agreed that the matter of pronunciation should receive attention in the next Pharmacopeia.

LEGAL CONTROL NECESSARY IN THE TREATMENT OF DRUG HABITS.

DR. FREDERICK H. GERRISH, Portland, Me.: After speaking of the wide prevalence of drug habits, Dr. Gerrish emphasizes the futility of depending upon the victim's will power. Physical restraint is necessary in almost every case. And yet if the physician interferes with the freedom of action of the victim, even with his consent, he makes himself liable to a subsequent suit for false imprisonment. The only way to reconcile the conflicting interests of physician and patient is by the enactment of a law by which the victim can relinquish his freedom long enough to ensure a cure. Such a law was enacted in Maine in 1905. Dr. Gerrish had heard no complaints that its workings were other than salutary. The paper closes with a statement of the law.

(To be continued.)

Book Reviews.

Morris's Human Anatomy. A Complete Systematic Treatise by English and American Authors. Edited by HENRY MORRIS, A.M. and M.B. Lond., F.R.C.S. Eng., President of the Royal College of Surgeons of England, and J. PLAYFAIR MCMURRICH, A.M., Ph.D., Professor of Anatomy, University of Michigan. In five parts. Fourth edition, revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1907.

Among the composite works on anatomy the comprehensive treatise by Morris which goes under the name of "Morris's Anatomy" takes a prominent place. So successful has this book been, not only abroad, but in this country, that this latest, fourth edition, has been in part revised and rewritten by American anatomists. This has necessitated a very complete revision, and many of the articles, notably those on the muscles, central nervous system, sense organs and the skin, have been wholly rewritten. The complete list of contributors to this edition is as follows: Henry Morris, F.R.C.S., London; R. J. Terry, Washington University, St. Louis; Peter Thompson, King's College, London; Irving Hardesty, University of California; G. Carl Huber, University of Michigan; J. Playfair McMurrich, University of Michigan; Abram T. Kerr, Cornell University; Charles R. Bardeen, University of Wisconsin; Florence R. Sabin, Johns Hopkins University; R. Marcus Gunn, F.R.C.S., London; and W.H. A. Jacobson, F.R.C.S., Guy's Hospital, London.

The illustrations have been changed. Some have been excluded or dropped from this edition and others added. The book at present contains 1,025 illustrations, 319 of which are printed in colors. A notable feature of the book is the adoption of the Basle nomenclature in its entirety. This is the first anatomical textbook in English which has gone so far as this in reformed terminology, and it will no doubt do its part toward making universal a nomenclature which probably the best interests of the anatomical sciences demand. A notable feature of this fourth edition is that it may now be had in five parts, books naturally of varying size but all convenient to handle. These parts are arranged as follows: Part I, morphogeny, osteology, articulations; Part II, muscles, circulation and lymphatics; Part III, nervous system and organs of sense; Part IV, digestion, respirative and reproductive organs, ductless glands, and skin; Part V, surgical and topographical considerations. The advisability of dividing into volumes what is otherwise a ponderous book is not to be questioned. It furthermore makes possible the purchase of a single part by students of special subjects. The book may, however, still be had by those who prefer, in its original one volume form. The arrangement, printing and general form leave nothing to be desired from the point of view of the bookmaker's art. We can most cordially, as we have its predecessors, commend this new edition to the attention of anatomists, particularly surgeons, and others interested in the anatomical sciences.

The Climatic Treatment of Children. By FREDERICK L. WACHENHEIM, M.D., Chief of Clinic, Children's Department, Mount Sinai Hospital Dispensary, New York. Pp. 400. New York: Rebman Company. 1907.

This work certainly goes a long way to fill the vacant place in medical literature for which the author states it is intended, that is, the climatotherapy of early life. He first takes up the general principles of climatology and then that of temperate North America. He describes the various health resorts, both here and abroad, in more or less detail, not only as to their climate but also as to their sanitary and sociologic conditions. Much attention is given to the climatic management of the normal child. We especially recommend a perusal of his remarks on "hardening" to those vain and foolish mothers and more foolish physicians who advise bare necks and uncovered extremities during our northern winters. The book closes with chapters on the climatic treatment of constitutional and visceral diseases, scrofulosis and tuberculosis, and also contains a number of valuable charts. It is well worthy of careful reading, and cannot fail to be of assistance to every practitioner.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, OCTOBER 31, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 Boylston Street, Boston, Mass.

THE DEVELOPMENT OF THE WORK OF THE MASSACHUSETTS STATE BOARD OF HEALTH.

At the second quarterly meeting of the Worcester North District Medical Society, held in Fitchburg, Oct. 22, 1907, Dr. William C. Hanson, assistant to the secretary of the Massachusetts State Board of Health, presented a paper on Some Phases in the History, Development and Present Work of the Massachusetts State Board of Health. In this paper mention was first made of a remarkable document written by Lemuel Shattuck, and presented to the Massachusetts Legislature of 1850, with special reference to the following suggestions and recommendations contained therein:

(1) That "one of the most valuable reforms which could be introduced into the present constitution of society would be that the advice of the physician should be sought for and *paid for* while in health to keep the patient well."

(2) That "a general central board of health be established."

(3) That there be "far more efficient local boards of health."

(4) That there be "some intermediary between the central board of health and the local boards."

(5) And, finally, that the "cause of consumption and the circumstances under which it occurs be made the subject of particular observation and investigation," on the ground that "if consumption is ever to be eradicated or ameliorated, it can only be done by preventive means and not by cure."

Attention was called to the fact that the first meeting of the State Board of Health of Massachusetts, the first state board of health in this country, was held at the State House on Sept. 15, 1869.

A portion of the first communication of the State Board of Health to the boards of health of the various cities and towns of the Commonwealth was read, and many subjects of inquiry on the part of the board during the first two years of its existence were commented on, especially those relating to the cause of typhoid fever, and to the health of minors in factories. It was pointed out that in spite of the report of the State Board of Health of 1871, of the advisability of considering further the health of minors employed in factories, and notwithstanding the facts gathered and published in that notable report of 1850, relative to the causes of consumption and the inference drawn that "if the mortality produced by this disease is ever to be lessened, it is to be effected by preventive means," it remained for the Legislature of 1907 to pass an act providing for a better care of minors working in manufacturing establishments, and for the prevention of the spread of tuberculosis.

It was further pointed out that the recommendation of Lemuel Shattuck for the appointment of some intermediary between the State Board of Health and the local boards was provided by this same Legislature of 1907, by requiring the establishment of health districts and the appointment of state inspectors of health.

Brief mention was made of the first law relating to the sale of food and drugs, in 1882; of the enactment of the patent medicine law of 1906, emphasizing the section relative to the sale of proprietary preparations containing cocaine, and of the efficient enforcement of these laws by the State Board of Health. Attention was called to a communication recently issued by Governor Guild, that "the State Board of Health, with the full approval of the Governor, is now visiting chief dairies of neighboring states, and examining the premises; that the lack of uniform legislation between the states on this subject is laying an unfair burden on the State Board of Health of Massachusetts, which is compelled to act as a board of health, as far as herds from which milk sold in Massachusetts is concerned, not merely for this Commonwealth, but for several other states in addition."

The act relative to the general oversight and care of the purity of inland waters by the State Board of Health was referred to, as well as the work of the board, as to advising the author-

ities of cities and towns, corporations, firms and individuals, regarding existing or proposed systems of water supply and sewage.

Emphasis was laid upon the fact that Massachusetts was the first state in the Union to provide for the distribution of diphtheria antitoxin to anybody who needed it, whether rich or poor, and a statement was made to show that through the widespread distribution of antitoxin by the State Board of Health, the mean fatality during the antitoxin period, 1895–1905, was 12.4% ratio of deaths to cases, or less than half as much as during the three years preceding 1895 in the pre-antitoxin period, which was 28.3%.

It is interesting to observe that after the lapse of upwards of half a century the same questions have again arisen for the consideration of the State Board of Health as those which Lemuel Shattuck clearly brought to attention in 1850. It is, perhaps, less a subject for congratulation that definite legislative action has been postponed to so late a date. Lemuel Shattuck's attainments have not been regarded at their just worth, and we therefore, at this time, are glad to call attention to his pioneer work in matters of importance to the public health and welfare.

INTERCHANGE OF MEDICAL TEACHERS.

THE facilities of travel have so greatly increased during the past few years and medical men are coming to know so much more of the work of others in their own and other countries, that a definite interchange of teachers in our medical schools might easily be arranged. As is generally known, such an interchange has for some years been in practice between certain American, German and French universities in other departments than medicine with results which certainly justify a continuance of the practice and its further development. There is no sufficient reason why a similar interchange of teachers should not take place between medical schools of this and foreign countries. In fact, a beginning has already been made through such a course of lectures as that given by Prof. Pierre Janet, of Paris, a year ago at the Harvard Medical School, on Hysteria.

Many men in the medical profession are devoting much of their time to teaching and to investigation to the exclusion of practice. Others are apparently finding more and more time to give to the less practical affairs of their work, so that there certainly would be no difficulty in arranging for courses of lectures by men eminent in the medical sciences to be given at other than their own universities. The advantages of such an interchange are manifest. It has always happened, and will continue to do so in the future, that certain medical schools are for a longer or shorter period pre-eminent in one or several branches of medicine, depending upon the men who at any given time are actively engaged in special investigations. It is altogether fitting that the results of such investigations should be presented to as large and varied audiences as possible. It is, furthermore, not to be questioned that many of these men would be glad to make the small personal sacrifice required in traveling to another city and there delivering a course of lectures to its medical students and others who might be interested.

If such a plan were inaugurated, the lectures given should be primarily addressed to students of medicine, rather than to those already in practice. There is no more appreciative audience than a body of intelligent young men who have their ways in the world still to make, whose minds are receptive and who are eager for knowledge. Lectures, therefore, given at the medical schools by the best and most productive men of other cities could not fail to elicit enthusiasm from the student body and be of wide profit in the dissemination of recently acquired knowledge. Nor is there any reason why such a system might not be extended to English and continental universities and courses of lectures on medical subjects arranged on the same general basis as those already existing in the academic departments of several of our colleges.

Perhaps the greatest difficulty in arranging such courses for students is that of finding available time in the already overcrowded curriculum. It might necessitate giving up certain lectures or exercises already prescribed, but the ultimate benefit would, in our opinion, far counterbalance the slight disadvantage arising from a temporary interruption of a set course of instruction. In the rapidly advancing art of surgery, for example, there is ample opportunity for such an interchange of teachers as we have suggested. It would be well if the special surgery of the nervous system could be presented by a man whose time is largely given to that difficult branch. It is not to be doubted that a course of lectures from Sir Victor Horsley would do much toward exciting an interest in this subject, which is too likely to wane in schools where neurological surgery has not yet been adequately recognized.

The same is, of course, true of almost any subject in the range of the medical sciences.

It is not to be questioned that America has much reason to feel a just pride in the development of the teaching of medicine. The opportunity is certainly offered of becoming a pioneer in this further extension of its scope. Constituted as our American universities are, it is impossible for students, until the completion of their course, to learn of the methods of other schools and teachers, unless a plan of interchange is arranged. Naturally, this situation does not arise in the German universities, in which the student goes from university to university, and thereby has an exceptional opportunity of sitting under many great teachers. We look forward with confidence to a systematic plan of interchange, beginning possibly in a small way, but developing into a recognized and definite part of the medical curriculum.

AN ABUSE UNDER THE PURE FOOD LAW.

The secretary of the Massachusetts State Board of Health, in an address at the Harvard Medical School, Feb. 3, 1907, made the statement that "much power for good or for evil has been placed in the hands of the national pure food commission," and that "large powers have been delegated to practically one man in the nature of fixing standards and making regulations."

Leaving aside the many incongruous conditions and possibilities which might be cited as arising from the passage of the national pure food law, there is one regulation which is so abused that the harm to which it gives rise is destined easily to offset the good ensuing therefrom. One of the sections of the act provides for a guaranty, which is, in effect, an agreement by the manufacturer, packer, wholesaler or jobber, that he will hold himself responsible for the goods furnished by him to dealers. When a guaranty is filed with the Secretary of Agriculture, the package containing the goods bears the statement, "Guaranteed under the Food and Drugs Act, June 30, 1906. Serial No. ——."

In the Food Fair, now being held in Boston, is a booth arranged for the purpose of advertising a preparation known as "Celero," or "a headache lozenge." While the envelopes used for the distribution of the lozenges bear a statement that each lozenge contains two grains of acetanilid, the assertion is also made that the lozenge is a safe and convenient remedy for all forms of headache and neuralgia. Following this statement are the words, "Guaranteed under the Pure Food and Drugs Act, June 30, 1906," which are followed immediately, in a much larger sized and far more conspicuous type, by the words, "Eat it like candy — no water needed." Many of the lozenges are kept in bulk, on the counter, in a large, uncovered glass dish, such as is used by confectioners for candies, and in several instances, in the course of a few moments' observation, a small handful of the tablets was taken by the person in charge of the booth, and given to persons coming to the booth, with such remarks as the following: "The only harmless preparation on the market; nothing injurious about it whatever; will positively cure your headache." In one instance the saleswoman was observed to put a lozenge in the mouth of a young person, as if it were candy. In another instance a young girl came to the booth, saying, "Girlie, my little girl has got a headache; give me some of them." A small handful was put into an envelope and given to this girl. At another time a boy, who appeared to be about sixteen years of age, was in charge of the booth, giving away the lozenges in the same free and indiscriminate manner.

Large sized advertisements are posted on the booth, emphasizing the fact that these lozenges may be "eaten like candy." In a circular, which is sent out with the lozenges, directions are given to "Eat the lozenge like candy, at any time, before and after meals, in any place or under any conditions." The phrase, "Eaten like candy," is repeated in a conspicuous and heavy type.

MEDICAL NOTES.

Plague. — Up to Oct. 26, seventy-six verified cases of bubonic plague have occurred in San Francisco, with forty-eight deaths. Several suspicious cases have also appeared in Seattle, and one unquestioned case. The Marine-Hospital Service is taking charge of the situation, as in San Francisco.

Pilgrimages from Egypt. — According to the *British Medical Journal*, the annual pilgrimages from Egypt are ever a source of trouble and anxiety to the Egyptian Government, for such collections of the dirtiest and most insanitary people afford many occasions for epidemics of cholera, plague and other diseases to flourish. Several reports published under the auspices of the Conseil Sanitaire, Maritime, et Quarantenaire d'Egypte, for 1907, deal with the health of those assemblages. Fortunately plague and cholera appear to have been absent, but other diseases carried off their annual quota.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Oct. 30, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 67, scarlatina 44, typhoid fever 16, measles 4, tuberculosis 61, smallpox 0.

The death-rate of the reported deaths for the week ending Oct. 30, 1907, was 21.05.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, Oct. 26, 1907, was 192, against 204 the corresponding week of last year, showing a decrease of 12 deaths and making the death-rate for the week 16.43. Of this number 109 were males and 83 were females; 190 were white and 2 colored; 117 were born in the United States, 66 in foreign countries and 9 unknown; 43 were of American parentage, 119 of foreign parentage and 30 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 45 cases and 6 deaths; scarlatina, 33 cases and 0 deaths; typhoid fever, 22 cases and 0 deaths; measles, 8 cases and 0 deaths; tuberculosis, 50 cases and 15 deaths; smallpox, 0 case and 0 deaths. The deaths from pneumonia were 13, whooping cough 0, heart disease 30, bronchitis 4 and marasmus 5. There were 18 deaths from violent causes. The number of children who died under one year was 36; the number under five years, 48. The number of persons who died over sixty years of age was 47. The deaths in public institutions were 64.

There were 1 case and 0 deaths reported from cerebrospinal meningitis during the week.

DIPHTHERIA. — It is reported that the public schools of Rockland, a town near Brockton, Mass., have been closed because of an outbreak of diphtheria.

BEQUEST TO HOSPITAL. — By the will of Mrs. Susan E. Hoyt, a fund which will eventually amount to $20,000 has been left to the Stamford, Conn., Hospital, to provide free beds.

OPENING OF THE CHANNING HOME, BOSTON. — The Channing Home for Chronic Tuberculous Women on the corner of Bellevue and Francis streets, Boston, was formally opened on the afternoon of Thursday, Oct. 31.

NEW ENGLAND PHYSICIANS' CLUB — A club to be known as the New England Physicians Club, to be composed largely of physicians and dentists, has been incorporated in Massachusetts. It has secured for a clubhouse a desirable building on Boylston street. The president is Dr. P. J. Kingsley, and the secretary, Dr. William R. Brown.

SCHOOL HYGIENE. — At the annual meeting of the Massachusetts Schoolmasters Club, held Oct. 26, Dr. Thomas F. Harrington, Dr. Robert W. Lovett, both of Boston, and Dr. John J. Cronin, of New York, assistant chief of Medical Inspection of the Department of Health, made addresses. Dr. Harrington drew attention to the fact that there is no such thing as a system of hygiene, but that it is peculiarly personal and local in its applications.

NEW YORK.

COMMENCEMENT EXERCISES. — The thirty-second annual commencement of the New York City Training School for Nurses, on Blackwell's Island, was held on Oct. 19. There were thirty-three graduates, and Dr. Edward Sprague Peck, head of the medical board of the City Hospital, presided at the exercises.

MEDICAL DIRECTORY. — The Medical Directory of New York, New Jersey and Connecticut for 1907, just issued by the Medical Society of the State of New York, contains the names of 15,775 registered physicians, of whom 12,168 are in New York State, 2,317 in New Jersey, and 1,292 in Connecticut. Four thousand three hundred and seventy-six are credited to the Boroughs of Manhattan and the Bronx, 1,589 to Brooklyn, 129 to Queens, and 62 to Richmond, a total for the City of New York of 6,156 (as against 6,034 last year); while the physicians residing in the rest of the state number 6,012.

STREET CLEANING. — A public meeting was held on Oct. 18, under the auspices of the East Side Physician's Association, to discuss "The Street Cleaning Department in Relation to the Health of the City." Dr. Robert Abrahams, president of the association, presided, and the principal speaker was Dr. Walter Bensel of the Health Department, who for the past three months has done admirable service as acting Commissioner of Street Cleaning. Dr. Bensel told of some of the difficulties which the department had to contend with and of proposed plans for more efficient work, and concluded by saying that there was no question but what the people of New York could have clean streets if they would spend the necessary money.

WAS NOT HYDROPHOBIA. — Dr. Charles W. Dulles, of Philadelphia, recently noticed in a

newspaper an item to the effect that a dogcatcher, after being bitten in the course of his career by more than 250 dogs, was dying of hydrophobia at St. John's Hospital, Yonkers. He made an investigation of the case, and has sent a letter to one of the New York papers in which he gives the following account of it: "This interesting narrative, if true, would have furnished me with the second case only in this country charged to so-called hydrophobia that I have found in twenty-five years, of any dog catcher, keeper of a public pound, or manager or worker in a public or private kennel — that is, in the class of persons most bitten by sick, vicious and so called mad dogs. So I followed my custom and wrote at once to the chief resident physician of St. John's Hospital for the facts of the case. His reply is conclusive. 'Isaiah Lee did not have hydrophobia. The diagnosis was cerebrospinal meningitis. Newspaper account was incorrect. He died this afternoon.'"

Opening of New Jersey Sanitarium for Tuberculosis. — On Oct. 24, Governor Stokes formally opened the New Jersey Sanitarium for Tuberculosis, at Glen Gardner, Hunterdon County, in the presence of a number of prominent persons, including state officials and members of the legislature. The building is 107 by 85 feet and two stories high, and will accommodate somewhat over one hundred patients.

Elevation of Standard at Cornell University. — In his annual report to the trustees of Cornell University, made public at Ithaca, on Oct. 25, President Schurman recommends plans for the elevation of the standard of education in all the departments of the university. For entrance to the medical department, he would require the degree of Bachelor of Arts and also satisfactory evidence of the student's having pursued special courses in physics, chemistry and biology.

Cross River Dam Completed. — The last stone in the completed Cross River Dam at Katonah, Westchester County, was laid by President John F. Cowan, of the Aqueduct Commission, on Oct. 26, the exercises being participated in by various city officials, the members of the different water supply commissions, and the engineers under whose direction the rapid completion of the work had been accomplished. It is estimated that this new large dam, by the additional resources from the Croton system, which it renders available, will increase the city's water supply to such an extent as will suffice until the completion of the great Ashokan reservoir in the Catskill Mountains.

Two New Hospitals. — Commissioner of Charities Hebbard has just awarded contracts for two new hospitals, one at Coney Island and the other on Staten Island, Borough of Richmond. The Coney Island hospital, which will be the first city hospital to be erected in Brooklyn for thirty years, is to be a building of reinforced concrete, four stories in height, and to cost $283,475. It will be used for acute and general medical and surgical cases. The Staten Island hospital is to consist, when completed, of eight buildings, for which an appropriation of $2,000,000 has been made. The present contract is for six of these buildings. The institution, which will be known as Sea View Hospital, is to be located at Spring Valley, Manor Road, on an eminence overlooking the lower bay. The pavilions will be four stories in height and of reinforced concrete, and the completed hospital is designed to accommodate 800 patients. The altitude of the location and its proximity to the sea will, it is believed, make the hospital of special value for convalescents.

Examination by Teachers of Sight and Hearing of School Children. — The State Department of Health has just made a new departure in sending to each of the 446 incorporated villages in the State a "complete set of forms with instructions" for the examination by the teachers of the sight and hearing of all children in the public schools of these villages. The wisdom of this proceeding would seem to be very problematical, for, notwithstanding the completeness of the forms and instructions, it is scarcely to be doubted that many defects of vision which, if left untreated, may be attended by very serious consequences are likely to be overlooked by the examining teachers. As one observer has very well remarked, "The action of the department at least indicates that some appreciation of the importance of eyestrain in its relations to the efficiency and character of children has at last made its way into the official mind, and for that reason it is a cause for hearty congratulation; but we would like to know just what the teachers are expected to do, and whether the children found to have defective vision are to be sent to oculists for treatment or to opticians for maltreatment."

Verdict against Physicians. — In the first suit of the kind said to have ever been tried in the State of New York, Mrs. Ellen E. Kenyon-

Warner, a writer, recently secured a verdict in the Supreme Court for $25,000 damages from Drs. Flavius Packer and Sidney D. Wilgus, of New York, on the charge of having improperly adjudged her insane and caused her commitment to the State Hospital at Middletown. The plaintiff's claim was for $50,000, and the case was tried at New City, the county seat of Rockland County, before Justice Morschhauser, who in his charge to the jury stated that the principal question involved was whether the physicians had exercised due care in their examination of the patient. For the defense appeared such well-known alienists as Dr. Charles W. Pilgrim, superintendent of the Hudson River State Hospital for the Insane at Poughkeepsie, and Drs. Charles L. Dana and Bernard Sachs, of New York. Dr. Dana was obliged to leave before finishing his evidence, but subscribed to the entire testimony of his colleagues. Drs. Pilgrim and Sachs, in answer to a hypothetical question, embodying the points for the defense as brought out in the testimony, expressed the opinion that a person performing the acts alleged must be of unsound mind. On cross examination, however, they admitted that some of the things mentioned did not of themselves establish insanity.

Sanitation in South America. — Dr. Louis L. Seaman, of New York, who has just returned from a five months' tour of South America, states that he was greatly impressed with the campaign of sanitation which is being carried on in the principal cities of the republics there; a campaign that is destined, he believes, to make the harbors of South America as disease-proof as any in the world, and which will insure for those countries a leading place among the nations of the earth. The great problem with them, he says, has been that of health, and the way they are solving it is an object lesson to the whole world. Rio Janeiro, a city whose harbor was one of the world's black spots, from a health standpoint, a few years ago, is now as safe as any on the globe, and this is entirely due to the admirable sanitary administration, under the direction of Dr. Oswaldo Cruz, the Health Superintendent, now in operation there. The same is measurably true, also, of the various other harbors and large cities of South America. There is hardly a city of importance on the seaboard which has not had bubonic plague to deal with from time to time, and this disease has now been thoroughly mastered. In Rio there is a reward of five cents for every rat killed, and to secure this it is necessary to send the dead animals, ticketed with the street and number of the houses from which they came, to certain specified depots. From thence they are immediately taken to Dr. Cruz's laboratory, and whenever a rat shows evidences of the plague, a health squad, organized like an American fire company, hurries to the house in which it was killed, and, irrespective of the character or ownership of the place, tears down the ceilings and thoroughly disinfects the place.

The Mosquito as a Sanitary Problem. — The Wesley M. Carpenter lecture at the New York Academy of Medicine was delivered on Oct. 17 by Dr. Edward A. Ayres, of New York, and Monmouth Beach, N. J., whose subject was "The Mosquito as a Sanitary Problem." In the course of it he declared that the mosquito had destroyed more human beings than are living in the world to-day, and that in addition to being the agent responsible for malaria and yellow fever, it was probable that it stood in the same causative relation to beri-beri, which had cost thousands of Asiatic lives. "The mosquito," said Dr. Ayres, "has had more influence than climate in demarcating tropical from temperate zonal occupation by the races of men. A female mosquito, caught in a sudden congelation of a drop of dew, can sleep peacefully through the winter months and when the spring sun sets her free can lay four hundred hatchable eggs. One healthy, favored pair of early June mosquitoes can start a progeny that will rival the human population of the globe ere the harvest moon; yet one man with a spade can destroy more mosquitoes in an hour than mankind numbers at any one time." Having paid a tribute to the self-sacrificing medical men whose researches had proved that the mosquito was the carrier of yellow fever and other diseases, the speaker stated that he had coined a new word for the class of diseases for which the mosquito was responsible, namely, "homosquitic." The closing portion of the lecture was devoted to the matter of the extermination of mosquitoes, which Dr. Ayres declared was feasible, economical and less difficult than was generally supposed; and he gave a number of examples of the effective work done in New Jersey in draining thousands of acres of marsh land which from time immemorial had been the favorite haunts of the pest. The cost of swamp drainage in New Jersey, Staten Island and Long Island, he said, varied from $1.50 to $2.50 an acre, and one man could keep 75,000 feet of ditches in good condition from year to year.

8. *Silkman, A. *The Diagnosis of Glanders in the Human Subject from the View Point of the Veterinarian.*

8. Silkman says that glanders in the human subject is not very rare. Many cases go undiagnosticated on account of their resemblance to typhoid fever, pneumonia, or sepsis. Acute glanders runs a course of twelve to eighteen days. The subacute cases last from six to eight weeks. The Widal and glanders agglutination tests are of value in diagnosis. In the beginning the symptoms are much like those of typhoid fever, with a high and very irregular and uncontrollable temperature. Next the symptoms of pneumonia develop. Then come articular symptoms resembling rheumatism. Abscesses now form which are not relieved by evacuation. Three or four days before death pustules appear on face, neck and shoulders, which rupture and leave rough, uneven ulcerations. The lymphatic glands are often involved. Illustrative cases are given.

2. Under this very broad heading the writer discusses the relative death-rate from tuberculosis among the American Indians, the Japanese and Chinese in America, and the native whites. He does not mention the negro. The Sioux Indians, who are the flower of the Indian tribes, living in a healthful climate, well fed and comfortably housed, show a death-rate from tuberculosis of more than fifteen times that of the whites. The death-rate from tuberculosis of the Japanese in America is approximately that of the surrounding whites. That of the Chinese is almost double that of the whites, due probably to their extremely unsanitary surroundings. The writer finds an analogy to tuberculosis among the Indians in the frightful susceptibility of the aborigines the world over to the infectious diseases of civilization. The Indians have derived their tubercle bacilli from the white men, hence they are of the same strain. Yet working in the virgin soil of the American Indians, the same tubercle bacilli produce a rather different and much more virulent disease. Among the Indians the average duration of the entire disease is only four to six months. [R. I. L.]

9. Senn, N. *Travel Notes from South America.*

1. Beebe finds a dearth of accurate knowledge of the physiology of the thyroid gland. He considers the thyroid apparatus as one of the vital viscera. This apparatus consists of two well differentiated structures, (1) thyroid gland, and (2) parathyroid glands. Experimental removal of the thyroid causes cachexia, alleviated by the administration of thyroid substance. Removal of the parathyroid glands causes an acute fatal tetany in a few hours to a few days. Hypodermic injection of beef parathyroid nucleo-proteid will prevent death in the acute tetany, but the animals have all died within three weeks. Chemical studies have shown that the normal thyroid gland contains little nucleo-proteid and albumin, but much globulin. This thyreoglobulin contains the iodin, and it is to this combination that thyroid extracts largely owe their activity. The normal parathyroid contains little globulin and albumin, but much nucleo-proteid. In most thyroid glands removed from cases of exophthalmic goiter chemical examination shows a marked increase in the nucleo-proteid. In simple goiter there is a relatively large amount of globulin poor in iodin. Cases with exophthalmic goiter have a much increased nitrogen metabolism and a low kreatinin output. It has been impossible to produce exophthalmic goiter experimentally, but many of the symptoms of the disease are seen when thyroid substance is given in excess. The hypersecretion theory seems most satisfactory, but there has been no explanation of the mechanism of the production of symptoms.

2. MacCallum has studied the thyroid glands removed from sixty patients, suffering from some or all of the symptoms of exophthalmic goiter. As a rule the changes in the thyroid gland are similar and apparently characteristic. The gland is usually slightly enlarged. The section surface is tougher, dryer and more granular than normal. This change may be patchy, but usually is general. Microscopically, the alveoli are no longer round and full of colloid, but are irregular and contain epithelial projections. The epithelium is columnar rather than cubical. The lumen is markedly encroached upon and there is much less colloid. The amount of colloid varies greatly, but it seems that it may bear a fairly constant relation to the stage of the disease, and that while the presence of quite abundant colloid is not inconsistent with the development of intense symptoms, yet in most cases in which the symptoms are intense, the colloid tends to disappear with the advance in the alterations in the gland. The only constant lesions found elsewhere in exophthalmic goiter are in the thymus and the lymphatic apparatus. The thymus is enlarged. Histologically it is like the thymus of early years. Not only are there masses of lymphoid tissue in the thyroid gland itself, but the lymph glands generally, especially in the neck, are enlarged. This change has the appearance of being a reaction to the absorption of some poison, but whether this material stirs up the thyroid also to proliferation, or is itself the product of the over-active thyroid it is difficult to say.

6. Much has been written on arterial degeneration after the injection of adrenalin. Rabbits have been the animals used. Miles found arterial degeneration in 27% of rabbits receiving adrenalin, and in 34% of presumably normal rabbits not receiving adrenalin. One of the presumably normal rabbits presented calcareous deposit in the aorta and typical arteriosclerotic atrophy of the kidneys. [R. I. L.]

THE JOURNAL OF EXPERIMENTAL MEDICINE.
MAY 25, 1907.

9. *KRAMER, S. P. *The Pathogenesis of Gallstones.*

4 and 5. Noguchi describes experiments dealing with the influence of eosin upon the growth of the tetanus bacillus in cultures and in the tissues of inoculated animals. In cultures the presence of eosin in small proportions seemed to limit the spore formation, and in larger proportions to limit the growth of the bacillus. In inoculated animals the injection of eosin solution about the site of inoculation restricted the growth of the bacilli, and prevented development of the disease, although the bacilli remained alive and virulent to other animals. The action of the eosin injection was proved to be one of merely local immunity, since bacilli removed after a time from a site of inoculation treated with eosin and reinoculated in another part of the same animal not treated with eosin produced tetanus. Possible clinical applications of these findings are not discussed.

9. Kramer reviews the theories that have been held as to the cause of the formation of gallstones, and calls attention to the absence of experimental evidence bearing upon the action in this process of infections by typhoid and colon bacilli. He has conducted experiments which show that typhoid and colon bacilli growing in filtered and sterilized human bile and peptone bouillon solutions produce a heavy sediment containing all the constituents of gallstones. [F. W. P.]

THE LANCET.
OCT. 5, 1907.

6. Gifford reports in detail two cases of hyperplastic tuberculosis of the cecum which he operated on successfully. The first case both clinically and pathologically simulated malignant disease. The second case was evidently tuberculous and led to a re-examination of the first case, which was found also to be tuberculous. He refers to the literature on the subject, and speaks of the differential diagnosis between this condition and that of cancer. The treatment is surgical.

7. Teizo, who has made an extensive investigation of polymastia among the Japanese, in this paper gives the result of his studies on the relation of polymastia to tuberculosis. He concludes, (1) that cases of polymastia are found more among the tuberculous than among the non-tuberculous. The former are nearly twice as numerous as the latter. (2) That those who have polymastia are more liable to be affected by tuberculosis than those who have not. The difference between them is more than 15%. He gives the references to all works on this subject. No explanation of this peculiar state of affairs is given. [J. B. H.]

16. EDINGTON, G. H. *Hygroma Colli and Branchial Fistula.*

3. Ogilvie and Easton report two cases of hereditary dystrophy of the muscles of the shoulder girdle in a father and son. The father, aged forty-five, first noticed weakness in the shoulders when he was twenty-five years old. The condition has progressed steadily ever since, unaccompanied by any symptoms whatsoever except the increasing loss of power in both shoulders, and the gradual shrinking of the muscles in the neighborhood. The son, aged twenty-five, began to notice weakness of the shoulders two years ago, coming on without any cause, and except for this slowly progressing weakness he has experienced no symptoms. In neither case was there any history of a preliminary hypertrophy.

5. Dean opens a discussion on the relative value of inhalation and injection methods of inducing anesthesia. He gives in detail the method of administering stovain in lumbar anesthesia; he advises cotton in the patient's ears and either dark glasses or a screen so that they cannot see the operation. In five cases he gives the impressions of the patients with regard to this method of anesthesia. In the discussion which followed his paper the general opinion seemed to be that at present ether or chloroform anesthesia given by an expert is by far the best.

13. Maylard gives a long and careful exposition of transverse incisions in abdominal operations, with detailed reports as to the occurrence or non-occurrence of hernia in 16 cases. He concludes: (1) That when time is not of paramount importance more permanently secure scars result from transverse than vertical incisions. (2) Transverse incisions afford more room for the treatment of pelvic

diseases and are also better for exploratory purposes. (3) Vertical incisions involve the division of fewer blood vessels and the apertures can be closed by a single series of through-and-through sutures. For these reasons, where time is a serious consideration, they should be employed. (4) In dividing the sheath of the rectus the chief end to aim at is to carry the incision as much as possible in the line of the fibers of the aponeurosis, and that wherever possible the fibers of the rectus should not be cut but should be separated — serial suturing should be employed. (5) No operation should be performed unless absolutely necessary, when the patient has a cough which it is possible to cure or alleviate. Four weeks should be allowed at least after the operation for rest in a dorsal or semi-recumbent position, and two months more before any undue strain is exercised on the wound. [J. B. H.]

THE PRACTITIONER.

10. STILL, G. F. *Recent Work in Diseases of Childhood.*
11. *BRIDGE, J. C. *Infant Mortality and Fly Injection.*

2. Howell and Wilson give a careful paper on movable kidney in all its various aspects,— historical, anatomical and pathological. Three factors they say are responsible for the greater frequency of this condition in women than in men: (1) The greater shallowness of the renal fossæ. (2) The greater frequency of chronic constipation. (3) Tight lacing.

5. MacLennan reviews the subject of "Stauungshyperämie," and gives various practical points in the use of this method of treatment. He presents the more common objections to this method, and shows how the dangers and discomforts, such as pain, increased infection, bleeding, etc., can be avoided. He counsels the avoidance of tight bandaging as shown by the production of blisters on the affected part, and recommends that the physician should gain experience with the milder forms of sepsis before treating more severe cases, and that in all cases it is not a substitute for other means of treatment but an aid; that antiseptics and dry dressings should be used as they are needed. He describes in detail the technic. He states that this method is agreeable to the patient as well as efficacious; that shorter incisions are needed and fewer operations.

6. Flett presents cases in which he has used Bier's method of treatment with comments of a practical nature.

11. Bridge believes that fly infection of milk and other infants' food plays a large part in the etiology of infantile summer diarrheas. He quotes several cases in support of this view, and gives suggestions as to barn and house hygiene to prevent or diminish this source of infection.

[J. B. H.]

MÜNCHENER MEDIZINISCHE WOCHENSCHRIFT. No. 34.
AUG. 20, 1907.

1. OTTO, R. *On Anaphylaxis.*
2. BAER, G. *The Opsonic Index and the Results Obtained in Cases Treated with Marmorek's Antituberculosis Serum.*
3. *CURSCHMANN, H. *Hysterical Sweating.*

10. HARTLEIB. *Enchondroma of the Larynx.*
11. FEDERSCHMIDT. *Cheese Poisoning.*
12. HOFMANN, A. *A Simple Extension Apparatus.*

3. Curschmann reports two cases of long continued periodic sweating, occurring in a mother and daughter. They appeared two or three times daily, were of drenching character, unaccompanied by chill or by fever, and without any preceding hysterical manifestations (convulsions, etc.). During the attack the mind was clear, the patient quiet and peaceful, no preceding embarrassment or excitement was demonstrable. The sweats presented the picture of those resulting from the use of diaphoretics. Blood pressure and frequency of pulse were never increased. No organic changes in the central nervous system could be made out. Treatment by suggestion proved promptly effective in both cases. The author considers the etiology to have been hysterical. He has found no similar cases reported in the literature.

4. Since the eighteenth century a relation between croupous pneumonia and the acute attack of gout has been recognized. Ebstein reports three cases of his own and three from the literature, in which persons with a tendency to gout have experienced an acute attack following pneumonia. The gout appears after the pneumonia has begun to resolve, and is probably due to the fact that with the resolution of the exudate in the lungs, comes a destruction of cell elements, and a sudden setting free of nuclein bases and uric acid, which owing to the existing diminution in the nuclein metabolism precipitate the acute attack of gout.

5. Schlecht describes the new "capsula gelodurata" of Rumpel, which resembles the "glutoid capsule" of Sahli, differing only in that fluids can be administered as well as solids. A careful series of experiments has shown that the capsules are dissolved only in the intestine. They are extremely useful for the administration of drugs which upset the stomach, or whose action is primarily desired in the intestime. The author has had great success with this method of administering vermifuges.

[R. D.]

BERLINER KLINISCHE WOCHENSCHRIFT. No. 31.
AUG. 5, 1907.

1. ASCHOFF, L. *The Lower Uterine Segment and Placenta Previa.*
2. *CLAUS. *Syphilitic Affection of the Parotid.*
3. GRÜNBAUM, D. *A Case of Primary Carcinoma of the Appendix.*
4. *SCHANZ, A. *A Typical Diseased Condition of the Spinal Column.*
5. *HERZOG, B. *The Early Diagnosis of Syphilis of the Heart.*
6. PICK, L. *Menigococcus Spermatocystitis.* (Concluded.)

2. Claus reviews the literature of tertiary syphilis of the parotid gland, a condition of considerable rarity, and gives his observations of a case, a woman with a syphilitic history, who had a hard, non-painful swelling of both parotids, more pronounced on the left, associated with a left-sided chronic purulent otitis media. Under antiluetic treatment both the glandular enlargement and the discharge from the ear cleared up. The author considers that both conditions were of syphilitic origin.

4. Schanz describes a condition of the spinal column, marked by pain and tenderness over certain of the vertebræ, associated with tender points over the ribs and pelvic bones, without any evidence of an inflammatory process. This condition is usually accompanied by gastro-intestinal, or general nervous symptoms. The author considers this to be a condition very like the pain of flat foot. He recommends rest, followed by massage and gymnastics. A support worn about the thorax is of great aid. [The author offers no convincing evidence of any sort in support of this "new disease," the symptoms of which exactly resemble those of certain cases of neurasthenia.]

5. As a result of numerous observations, Herzog believes that the early diagnosis of syphilitic involvement

of the heart is possible, but only when the aorta and coronary arteries are affected. In every severe case of angina pectoris in the young or middle aged, in cardiac enlargement without other demonstrable cause, or in aortic insufficiency appearing in middle age without a preceding acute articular rheumatism, or other acute infection, syphilis should be always thought of as the probable causal factor. [R. D.]

No. 32. AUG. 12, 1907.

1. *PEL, P. K. *Is Opium Useful or Harmful in Acute Appendicitis?*
2. SELIGMANN, E. *Contributions to the Question of So-Called Absorption of the Complement.*
3. EYSBROEK, H. *The Specificity of Amboceptors.*
4. FINK, H. *Principles of the Different Karlsbad Gallstone "Cures."*
5. HEYMANN, H. *Operative Perforation of the Non-Pregnant Uterus.*

1. Pel believes that, in the hands of a carefully trained man, opium is of great value in the acute attack of appendicitis, especially in cases of beginning inflammatory process with walling off around the appendix. The rest which opium brings the gut hastens the walling-off process. It is unnecessary to give large doses, nor is morphine of advantage. The author uses tinctura opii in doses of from 5 to 10 drops, repeated till the pain is dulled and the patient is quieted. With careful observation, the symptoms indicating immediate operative interference are never masked. [R. D.]

1. *EWALD, C. A. *Myxoneurosis Intestinalis, with Some Remarks on the Technic of Rectoscopy.*
2. *SCHMIEDEN. *The Surgical Treatment of Exophthalmic Goiter.*
3. LOEWENTHAL, W., AND V. RUTKOWSKI, W. *The Action of Roentgen and Radium Rays on Trypanosoma Lewisii.*
4. WINTERNITZ, H. *The Testing of the Secretory Function of the Stomach by Means of the Test Meal.*

1. Ewald claims that it is clinically impossible to differentiate between enteritis membranacea, colitis mucosa, and myxoneurosis intestinalis. Neither the symptoms nor the stools show differences characteristic enough to warrant a diagnosis. Valuable data can, however, be obtained by use of the rectoscope. In the two former conditions evidences of inflammation, injected vessels, generally engorged mucosa, slight loss of tissue, with small adherent bits of mucus, are to be seen; in the latter the mucous membrane is pale, the mucus is more generally disposed, and, most important of all, the gut shows a marked tendency to spasm, so marked, indeed, as to lead to a suspicion of actual stenosis. The author considers this last as almost pathognomonic. He recommends a bland diet, which leaves a large, soft residue, and high enemata of oil and bismuth. He appends an excellent description of his technic of rectoscopy.

2. Schmieden reviews the symptoms of exophthalmic goiter, and agrees with the generally accepted theory of their thyrogenic origin. He believes that operative treatment is often too long delayed. An important contra-indication to operative treatment is the presence of advanced symptoms, particularly marked cardiac involvement. When the patient, seen early in the disease, does not react after a fair trial to medical treatment, operation for the removal of the gland should be at once resorted to. He has had excellent operative results. [R. D.]

The Ophthalmo-Tuberculin Reaction. COMBY (*Presse Médicale*, Aug. 10, 1907) has tried the ophthalmo-tuberculin reaction suggested by Calmette in two series of 16 and 53 children. His results agree absolutely with those of Calmette. In the first series he had two very violent reactions in the eye causing a conjunctivitis that took eight days to disappear. After this he reduced the strength of his tuberculin by one half; this he used on 108 cases with no bad results. The tuberculous individual reacts with a marked conjunctivitis with exudate, while a normal person shows at most a moderate injection without exudate. The other eye serves as a control for comparison. Any ocular lesion already present is a contra-indication against the use of this test. [J. B. H.]

The Ophthalmo-Typhoid Reaction. CHANTEMESSE (*Le Bulletin Médicale*, July 24, 1907) describes an ophthalmo-typhoid reaction similar to that of Calmette and Wolff-Eisner with tuberculin. By means of absolute alcohol he obtains a dry precipitate of the typhoid toxins; 1–50 mg. of this dissolved in a drop of water constitutes the dose used in this test. The results, he claims, are very decisive, whether positive or negative. In healthy persons or those suffering from a disease other than typhoid, there is only a mild injection of the conjunctiva, coming on in two to three hours and disappearing at the end of five or six hours. In the case of typhoid it is vastly more severe, reaching a maximum in six to twelve hours, and lasting eight to twelve more with a sero-fibrinous exudate and symptoms of a marked conjunctivitis. Although it is too soon to say definitely, this reaction seems to appear very early in the disease, in some instances earlier than the Widal reaction. [J. B. H.]

Thyroid Insufficiency. LEOPOLD-LEVI AND HENRI DE ROTHSCHILD (*Gazette des Hôpitaux*, June 29, 1907) contribute an interesting article with the title, "The Little Signs of Thyroid Insufficiency." Among the stigmata they mention transitory edemas without albuminuria, especially in the frontal and facial region, continued coldness of the extremities, cyanosis of the hands and feet, subnormal temperature, chilly feelings, an extreme sensitiveness to cold. Constipation is a common and persistent symptom. Such persons are very easily fatigued and have poor appetites. Headaches are frequent as well as muscle and joint pains; insomnia is common. Obesity, a sluggish mentality and precocious senility often appear. There are periodic auto-intoxications, and infections, vomiting spells without apparent cause, extreme nervousness. Such symptoms will often disappear under thyroid medication. [J. B. H.]

Miscellany.

"KULIN POLYGAMY."

A PRACTICE that goes by this name — an absurd one, since there is no polygamy about it in the sense in which we understand it — has lately been the subject of several letters published in the London *Times*, as we learn from last Sunday's *Sun*. It seems to prevail among the Bengalis. Some of the *Times's* correspondents approve of it as a means of improving the physique of a race; other speak of it as "revolting" and "abhorrent." Among those who defend it is that interesting person, Mr. George Bernard Shaw. It is well known, of course, that in most communities many women eligible to matrimony fail to form a marital alliance with a suitable man and consequently remain spinsters. Their reproductive capacity is wasted. The Bengal practice purports to spring from a patriotic desire to save this waste. Mr. Shaw says: "What does a Bengali father do under the same circumstances? He selects a picked man, a Brahman representing the highest degree of culture and character in his class, and pays him £700 to enable his daughter to become the mother of a well-bred child."

There is no pretense of marriage, as we understand it; the Brahman is simply hired to beget a child. If more children are wanted, presumably other picked men may be provided for the same woman, and perhaps that accounts for the use of the word polygamy. The whole business

seems to us to be on a par with the breeding of domestic animals. The farmer buys the service of a selected stallion for his mare; the rich Bengali hires a picked man to serve his daughter. We must agree with those who call the practice revolting and abhorrent. It is the effort of medical men to promote the physical welfare of all human beings, but never at the expense of morality and social order; consequently we expect that our British confrères will join us in protesting against approval of the strange Bengal custom. — *New York Medical Journal.*

IN HONOR OF ROBERT KOCH.

A movement for the foundation of an institution which is to bear the name of Robert Koch is on foot in Germany, and a committee has been formed for the purpose of collecting money for the object. The chairman is Dr. von Studt, Prussian State Minister; the vice-president, Privy Councillor Althoff; the secretary, Professor Schwalbe, editor of the *Deutsche medizinische Wochenschrift;* the treasurer, Dr. Paul von Schwabach, General Consul, Berlin. Among the members are Dr. Bumm, President of the Imperial Health Bureau, Berlin; Count Henckel, Prince von Donnersmarck, member of the Prussian House of Lords; Professor Ehrlich, of Frankfort; Professor Fiedler, some time physician-in-ordinary to the King of Saxony; Dr. von Böttinger, member of the Prussian Chamber of Deputies; Dr. Förster, director of the Cultus-Ministerium, Berlin; Prof. Bernhardt Fraenkel, of Berlin; Count von Posadowsky-Wehner; Chamberlain v.d. Knesebeck, Imperial Vice-Upper Master of Ceremonies; Surgeon-General Ilberg, physician to the Kaiser; the Bavarian Envoy in Berlin; the Ministers of the Interior of Saxony, Würtemberg, Baden and Hesse; and the Surgeon-General of the Prussian army. The institution, which is to be applied to the furtherance of research in all directions for the discovery of means of checking the diffusion of tuberculosis, is intended to be a permanent memorial of the discovery of the tubercle bacillus by Professor Koch twenty-five years ago. Appeal is made for contributions sufficient to make the institution a tribute of gratitude to Koch, similar to those with which the name of Pasteur has been honored in France and that of Lister in England. Contributions to the Fund should be addressed to the Treasurer, Dr. Paul von Schwabach, S. Bleichröder's Bank, 63, Behrenstrasse, Berlin. — *British Medical Journal.*

RESOLUTIONS AGAINST CONTRACT PRACTICE.

At an adjourned stated meeting of the Norfolk South District Medical Society, held in Boston Oct. 3, 1907, the following resolutions were unanimously adopted:

Whereas it has become a common practice with many of the Fellows of this society to engage in what is known as contract work or lodge work, and whereas this method of conducting business is unworthy of an honorable physician and derogatory to his professional character and standing, and also in the end a source of loss rather than a gain in income;

Therefore, resolved, That as a society we condemn contract practice in our profession, and we all will in the future refuse to consult with physicians engaged in this work (except possibly in a case of absolute emergency where a person's life is actually at stake) or to affiliate professionally with such persons.

Resolved, That all the Fellows of this society shall be required to sign a promise or statement that after the contracts which have already been made shall have expired, they shall refuse to make any further contracts under the penalties heretofore stated.

Resolved, That these resolutions be entered on the records of the society and a copy of the same be transmitted to the secretaries of the other district societies of this state and also be furnished for publication to the Boston Medical and Surgical Journal and the *Journal of the American Medical Association.*

Charles S. Adams, M.D.,
Secretary, Norfolk South District Medical Society.
Wollaston, Mass., Oct. 3, 1907.

Correspondence.

COLLECTIVE INVESTIGATION OF THE POLIOMYELITIS EPIDEMIC OF THE YEAR 1907 BY THE COMMITTEE APPOINTED BY THE NEW YORK NEUROLOGICAL SOCIETY, WITH THE CO-OPERATION OF THE COMMITTEE APPOINTED BY THE SECTION ON PEDIATRICS OF THE NEW YORK ACADEMY OF MEDICINE.

New York, Oct. 29, 1907.

Mr. Editor: The members of the committees above mentioned are anxious to make a thorough investigation of and to collect all the data relative to the epidemic of poliomyelitis of 1907 in New York City and its immediate vicinity. To this end they must have the co-operation of all those who have had, or will have, an opportunity of studying this disease in hospital or private practice. Physicians willing to assist in this work will kindly inform the secretary, Dr. Edwin G. Zabriskie, No. 37 West 54th Street, New York City, who will send history forms so as to secure uniform records. Physicians who cannot collaborate with the committee will confer a favor by reporting to the secretary the number of cases of poliomyelitis they have treated during the past six months.

The joint committee wishes to state most emphatically that due credit will be given to every one who contributes to this collective investigation, and that the publication of the committee's report will in no wise interfere with any article or articles to be published on this subject. Moreover, the committee's report will surely not be printed earlier than a year from date, so that medical men will have ample time to publish their articles long before the committee will have its report ready.

B. Sachs, *Chairman,* E. G. Zabriskie, *Secretary,* J. R. Hunt, J. F. Terriberry, L. Pierce Clark, Simon Flexner, for the Rockefeller Institute; C. F. Bolduan, for the Department of Health, New York City,
Committee of the Neurological Society.

L. E. La Fetra, Herman Schwarz, L. C. Ager, Brooklyn, *Committee of the Section on Pediatrics of the New York Academy of Medicine.*

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED OCT. 16, 1907.

G. W. STONER, surgeon. Directed to report at Washington, D. C., Oct. 22, 1907, for special temporary duty; upon completion of which to rejoin his station at Ellis Island, New York, Oct. 14, 1907.

P. M. CARRINGTON, surgeon. Granted leave of absence for 3 days from Oct. 14, 1907, under paragraph 189, Service Regulations.

T. CLARK, passed assistant surgeon. Directed to proceed to Allentown, Pa., for special temporary duty; upon completion of which to rejoin his station at Philadelphia, Pa. Oct. 14, 1907.

T. CLARK, passed assistant surgeon. Directed to report at Washington, D. C., Oct. 22, 1907, for special temporary duty; upon completion of which to rejoin his station at Philadelphia, Pa., Oct. 14, 1907.

J. W. SCHERESCHEWSKY, passed assistant surgeon. Directed to report at Washington, D. C., Oct. 22, 1907, for special temporary duty; upon completion of which to rejoin his station at Baltimore, Md. Oct. 14, 1907.

T. D. BERRY, passed assistant surgeon. Granted leave of absence for 1 month and 10 days from Nov. 1, 1907. Oct. 16, 1907.

A. J. MCLAUGHLIN, passed assistant surgeon. Directed to proceed to Paris, France, London, England, and Berlin, Germany, for special temporary duty; upon completion of which to rejoin his station at Naples, Italy. Oct. 11, 1907.

H. G. EBERT, assistant surgeon. Relieved from the U. S. Revenue-Cutter "Perry," and from duty at Seattle, Wash., and directed to report to Passed Assistant Surgeon Hobdy, San Francisco, Cal., for special temporary duty. Oct. 12, 1907.

W. H. FROST, assistant surgeon. Granted leave of absence for 15 days from Oct. 13, 1907. Oct. 10, 1907.

L. C. BEAN, acting assistant surgeon. Granted leave of absence for 28 days from Oct. 1, 1907. Oct. 11, 1907.

F. DUFFY, acting assistant surgeon. Granted leave of absence for 10 days from Sept. 6, 1907. Oct. 11, 1907.

C. M. FRISSELL, acting assistant surgeon. Granted leave of absence for 15 days from Oct. 15, 1907. Oct. 15, 1907.

K. S. KENNARD, acting assistant surgeon. Leave of absence granted Acting Assistant Surgeon Kennard for 28 days from Sept. 10, 1907, amended to read 26 days, only. Oct. 11, 1907.

B. ONUF, acting assistant surgeon. Granted leave of absence for 9 days from Sept. 26, 1907, on account of sickness. Oct. 11, 1907.

M. V. SAFFORD, acting assistant surgeon. Directed to report at Washington, D. C., Oct. 22, 1907, for special temporary duty; upon completion of which to rejoin his station at Boston, Mass. Oct. 14, 1907.

J. G. STANTON, acting assistant surgeon. Granted leave of absence for 15 days from Oct. 12, 1907. Oct. 11, 1907.

H. GAHN, pharmacist. Granted leave of absence for 12 days from Oct. 14, 1907. Oct. 11, 1907.

L. P. HALL, pharmacist. Excused from duty, without pay, for 10 days from Oct. 14, 1907. Oct. 14, 1907.

L. C. SPANGLER, pharmacist. Granted leave of absence for 23 days from Nov. 7, 1907. Oct. 16, 1907.

PROMOTION.

J. M. BELL, pharmacist. Promoted to pharmacist of the second class, effective Oct. 31, 1907. Oct. 14, 1907.

CASUALTY.

JOHN GODFREY, surgeon. Died at Detroit, Mich., Oct. 16, 1907.

APPOINTMENTS.

THE following appointments have been made to the staff of the Rockefeller Institute for Medical Research: DR. HIDEYO NOGUCHI promoted to Associate in Pathology; DR. G. W. HEIMROD, Assistant in Biological Chemistry; DR. W. A. JACOBS, Fellow in Biological Chemistry; MR. P. A. KOBER, Scholar in Biological Chemistry; DR. R. V. LAMAR, Scholar in Pathology.

DR. GEORGE L. WALTON has been appointed Consulting Neurologist to the Massachusetts General Hospital.

DR. HENRY C. BALDWIN has been appointed Physician to Out-Patients in Diseases of the Nervous System at the Massachusetts General Hospital.

The following appointments have been made at the Harvard Medical School: DR. J. D. BARNEY, Assistant in Anatomy; F. C. BLANCK, Research Assistant in Biological Chemistry; DR. E. N. TOBEY, Assistant in Bacteriology.

SOCIETY NOTICES.

FOUR LECTURES ON CLIMATOLOGY AND CLIMATO-THERAPY. — Dr. E. O. Otis will give a course of four lectures upon Climatology and Climato-therapy, illustrated by the stereopticon, upon successive Wednesday evenings in November, beginning Nov. 6, in the amphitheater of the Tufts College Medical School. Physicians, nurses and all interested in the subject are cordially invited to attend. The subjects are as follows: I. Nov. 6. The general principles of climate or meteorology. II. Nov. 13. Climatic features, classification of climates, characteristics of various climates. III. Nov. 20. Climatic or health resorts and their application to various diseases, especially to tuberculosis. IV. Nov. 27. The influence of climate upon man in health and disease.

NEW YORK AND NEW ENGLAND ASSOCIATION OF RAILWAY SURGEONS. — The Seventeenth Annual Meeting will be held at the New York Academy of Medicine, Thursday and Friday, Nov. 14 and 15, 1907.

CLINICAL LECTURES ON DISEASES OF THE SKIN. — The governors of the New York Skin and Cancer Hospital announce that L. Duncan Bulkley will give a ninth series of "Clinical Lectures on Diseases of the Skin," in the Out-Patient Hall of the hospital, on Wednesday afternoons, from Nov. 6 to Nov. 20, 1907, at 4.15 o'clock. The course will be free to the medical profession.

RECENT DEATHS.

DR. JOSEPH P. GRAY, a well-known practitioner of the Borough of the Bronx, New York City, died on Oct. 19. He was graduated from the College of Physicians and Surgeons, New York, 1882.

DR. HOSEA J. BABBIN, United States Navy, retired, died in Brooklyn, N. Y., on Oct. 25. During the Spanish-American War he was President of the Examining Board at the Navy Yard in Brooklyn, and later he was placed at the head of the Naval Hospital there. A short time since he was transferred to the retired list as Medical Director with the rank of Rear Admiral.

CUSHMAN DAY, M.D., M.M.S.S., died in Boston Oct. 26, 1907, aged twenty-five years.

BOOKS AND PAMPHLETS RECEIVED.

Annual Report of the Board of Health of the Department of Health of the City of New York for the Year ending Dec. 31, 1905. Vols. I and II. New York. 1906.

Annual Report of the Department of Health of the City of Chicago for the Year 1906. Chicago. 1907.

EXPERIENCE WITH OPSONINS AND BACTERIAL VACCINES IN THE TREATMENT OF TUBERCULOUS AND NONTUBERCULOUS ARTHRITIS.*

BY CHARLES F. PAINTER, M.D., BOSTON.

OBSERVERS of new phenomena lay themselves open to errors both of observation and interpretation. Particularly is this true when the phenomena concern problems, the solution of which has been sought long and diligently. There has never been a time when so many well trained men were working upon the problems of physiological chemistry and bacteriology as there are at the present day. At this time, also, great popular as well as professional and scientific interest has been aroused in the subject of tuberculosis, and, to a lesser degree, in chronic nontuberculous joint disease. Witness the money being advanced for the anti-tuberculosis crusade, and the attention devoted by all classes of society to attempts made to wipe out this curse. In the midst of all this popular enthusiasm and highly specialized scientific attainment, has come a new method which has much to recommend it from the theoretical and laboratory points of view. The questions at issue are, Do the clinical results correspond with the laboratory findings? Are the limits of error in methods of laboratory investigation so wide that the conclusions which seem legitimate from such observations may be erroneous? To the first of these questions only will the writer devote his attention.

The literature on opsonins and bacterial vaccines is getting to be quite voluminous, but the greater part of it is concerned with laboratory technic and theoretical considerations of the processes by which immunity may be brought about. A very few reports of clinical experience are on record, and many of these are valueless because of the paucity of data recorded, or because of the obvious inaccuracies of the observations.

Clinical experience must be the court of last resort in matters of this sort for many years to come. The human being is not a chemical retort into which reagents may be injected and results obtained which are identical with those we look for when experimenting in the laboratory upon the lower orders of animal life. Wonderful as have been the advances made, rational conservatism must be the prevailing state of mind of those who would not be carried away by their enthusiasm.

Attempting to put ourselves in this mental attitude, it is proper to review the facts. The laboratory side of the question has been thoroughly presented in the previous paper, and even though clinical experience cannot wholly bear out the brilliant results obtained along purely scientific lines, this does not in any way vitiate the results of such inquiry.

Successes obtained by some observers in the treatment of septic wounds, boils, acne, and similar localized infections, encourage the clinician to hope that there are as yet some ill-understood obstacles in the way of the application of the method to those conditions where it has failed. The good results in some other fields, notably in the treatment of diphtheria, by an analogous method, also offer much encouragement. One cannot read the literature covering the clinical experience of the writers without considerable misgiving as to the practical value of bacterial vaccination. Neither can he be particularly encouraged in the hope that the opsonic index is to be of advantage as a guide to the dosage or the repetition of inoculation. The consideration of its value as a diagnostic aid has not been extensively considered in the literature. Its value from this point of view, in the writer's experience, will appear in the course of this paper.

A few citations from current literature to show the character of the reports of clinical observers may not be amiss. These are cited because in most cases the writer believes acceptance of the findings at their face value would lead the uninitiated reader to improper conclusions regarding the efficacy of the method. French,[1] in the *British Medical Journal*, reports a case of tuberculous dactylitis and tuberculous disease of the os calcis, both having fistulæ. The child had a low opsonic index to the tubercle bacillus. One five thousandth mgm. of tuberculin "R" was given. A negative phase lasting nearly four weeks was the result. A second inoculation, again followed by a prolonged negative phase, was accompanied by some improvement. A third inoculation was given and the sinuses then promptly healed, and at the end of four months the writer says the patient was practically well. Such a case as this, even though it represents an observer's personal experience with bacterial vaccines in the treatment of tuberculous arthritis, should not be given much weight in determining the value of tuberculin in the treatment of bone disease.

Ohlmacher,[2] writing in the *Journal of the American Medical Association*, reports a remarkable series of cases of various sorts treated by bacterial vaccines. In determining the dosage and frequency of inoculation he was admittedly lax in the observation of the opsonic index, without which Wright himself, and Ross, the principal exponent of his technic on this side of the water, claim satisfactory results cannot be obtained. In spite of this failure the results were so uniformly good in all cases, he concludes that, with the possible exception of diphtheria antitoxin in the treatment of diphtheria, there is no more valuable reagent than bacterial vaccines for the treatment of many surgical infections.

Kellogg[3] finds the determination of the opsonic index of value diagnostically in the following reported case: A young woman consulted him because of a troublesome hip. There had been an injury to this joint some years previously, and she had been obliged to use crutches during all

*Read before The Massachusetts Medical Society, June 11, 1907.

[3] Kellogg: Northwest Med. Jour., vol. v, no. 1, p. 20.

this time. The head of the affected femur was dislocated. *One* observation showed the tubercular opsonic index to be .22. From this he concludes that the disease was a tuberculous one. In all probability this was true, but to have argued that it was because of *one* positive result in testing the phagocytic power of her leucocytes, constitutes a very insecure basis for such a conclusion. A second case is reported by the same author. A patient came under his care for a pleural effusion. The chest was aspirated, but guinea pigs inoculated with this fluid showed no signs of tuberculosis. A diagnostic dose of tuberculin was given and a typical reaction followed. Between July 12 and August 24, of the same year, she was inoculated with Koch's tuberculin, "R," not over three times (the record states at ten-day intervals). At the end of this period her physical signs had all cleared up and her weight had increased 7½ lb. I submit that the proof of the tuberculous character of her effusion is lacking, and that to offer such a case as a striking example of the curative value of tuberculin in such conditions is improper.

Wolff [4] reports some interesting results in the treatment of pneumonia by a pneumococcus vaccine. He feels that raising the opsonic power of the patient's serum in pneumonic cases was attended by more favorable results than attends the usual treatment of pneumonia patients, but thinks too few observations have been made to justify any positive assertion that such is the case.

Hollister [5] reports several cases too briefly to be of any scientific value. The general impression conveyed was that there was improvement, but not such as would be inconsistent with other and general treatment, simultaneously carried out.

Ross,[6] in a recent article, reports success in a number of cases of lupus, empyema, staphylococcus infection, endocarditis and Malta fever.

Bunch [7] refers to two cases where bacterial vaccines were employed to reinforce surgical treatment. He believes that this method offers great possibilties in the management of surgical tuberculosis by diminishing the negative phase produced by operating upon tuberculous foci, when the resistance of the patient has not been properly fortified. He also advocates the use of vaccines after operation during long periods, for the same reason. He cites a case of extensive lupus operated upon by Mr. Godlee. The operation was an excision of the lupoid tissue, followed by skin graft. Before the operation and for some time after, injections of tuberculin were carried out, in consequence of which he believes that the entire graft was successful. One one-thousandth mgm. was used at ten-day intervals. He also reports a case of acetabular hip disease which had been treated for one and one-half years, by apparatus and bed treatment, without any appreciable progress. An abscess developed, for which operation was performed. Just before operation 1-500 mgm. of tuberculin was injected, and this was repeated during the succeeding four months, at the end of which time the patient was reported as practically well. He also refers to an article of Turton's, in which 30 out of 34 cases of different sorts were treated with bacterial vaccines with very satisfactory results.

Fraser [8] reports 41 observations upon the opsonic power (tubercular) of the blood in healthy individuals. In the first place she attempted to establish a mean of variation. In the second place she compiled a table of 43 indices from individuals who were suffering from other diseases than tuberculosis. She also reports observations upon the tuberculo-opsonic index in nine members of tuberculous families. Her next series of observations was upon 91 cases of tuberculous disease. She found no striking diagnostic value in the tuberculo-opsonic index. In 58 of these cases the index was higher than that seen in health, while in 33 it was within normal limits. She found she could not classify her cases according to their indices as Wright claims to be able to do. The low index did not necessarily show a localized focus; neither did a high index, within the limits of variation, indicate a generalized process.

Brooke [9] refers to Bullock's remarkable series of staphylococcus infections reported in the *Practitioner* for November, 1905. Eleven cases treated with vaccines showed 9 prompt and complete cures.

There is a notable absence of clinical reports in German and French literature. This absence should have considerable more significance than does the too sanguine position of the observers to whom reference has been made. A few good results have been reported following the use of Marmorek's antituberculous serum, conspicuous among which are the cases cited by Hoffa in a recent article.[10]

In July, 1906, at the commencement of a four months' service at the House of the Good Samaritan, I began the treatment of tuberculous bone disease with Koch's new tuberculin. The inoculations have been kept up by my colleagues, Dr. Augustus Thorndike and Dr. J. S. Stone, during their services up to the present time. The patients upon whom this treatment had been tried were kept in the hospital in nearly every instance throughout this entire period, so that in addition to any benefit which may have accrued from these injections, they have had the benefit of sanitarium treatment. They were all advanced cases when treatment was begun, and were all children. In addition to these children I have followed the same treatment in a few cases of tuberculous bone disease in the adult, at the Carney Hospital. These patients had not the benefit of as good hygienic treatment as had the group at the Samaritan. It was not possible to keep them in the hospital for as long periods and they could not be controlled as well, because they were adults. They were all bad cases. The laboratory work

in connection with these observations was done through the courtesy of Dr. Leary at the pathological laboratory of the Tufts Medical School. In private practice I have also treated a few patients with bone tuberculosis in this way and in both private practice and at the Carney Hospital clinic we have treated several cases of chronic polyarthritis, of the rheumatoid type.

In brief detail the cases and results have been as follows (their charts have been shown in Dr. Leary's paper):

CASE I. Mrs. B., thirty years. Tuberculosis of the lumbar spine, the left ankle and the right great toe. Clinical diagnosis confirmed, so far as the ankle lesion was concerned, by histological examination of material removed at operation and by the tuberculous opsonic index. Patient had been under apparatus treatment for the Pott's lesion for two years and for the ankle one year. Ten injections of tuberculin were given, beginning with 1-10000 mgm. and going as high as 1-500 mgm. on two occasions. The Pott's lesion has made good progress; the ankle lesion was much worse than at any time for a period of three months, but has slowly been improving during the past four months; the lesion on the great toe has caused no trouble at any time during or immediately before the commencement of the injections. Rest and fixation have been enjoined throughout this entire period. The patient has gained in weight, improved in color and general condition, but no more so than has often been experienced in the same time and under the same conditions of hygiene and protective treatment.

CASE II. Mr. K., thirty-three years. Tuberculosis of mesenteric and retroperitoneal glands. Suppuration and mixed infection with the bacillus pyocyaneus. There is in all probability at this time an osseous involvement of the lumbar spine. There has been no pathological confirmation of the clinical diagnosis. The case has been under treatment for ten months and has had thirteen inoculations with tuberculin and a streptococcus and pyocyaneus vaccine. During the first five months of treatment there was considerable improvement in general condition and local signs, together with an almost complete closure of the sinus. The past six months his general condition has failed markedly; he has developed a very well defined phthisis, his sputum being loaded with tubercle bacilli, and the local signs in his spine have become much worse. His sinus is discharging very freely and death seems imminent at any time.

CASE III. Mr. A., twenty-nine years. Tuberculosis of left hip. Excision. Clinical diagnosis confirmed by histological examination. A very acute case of hip disease, said to be of only four months' duration at the time of admission to the Carney Hospital for excision of the head of the femur. Inoculation commenced before operation in the hope that his local and constitutional resistance might be built up. (*Vide opsonic chart.*) After operation there was a pyocyaneus infection and he was given pyocyaneus vaccine in addition to tuberculin. He was operated upon Oct. 17, 1906, and discharged Jan. 21, 1907. He improved slowly but reacted, it seemed, better than most cases of such severity, and since he left the hospital is reported to be doing well.

CASE VI. Miss M., forty-eight years. Tuberculous cervical adenitis. Phthisis. Chronic infectious polyarthritis. Glands in the neck suppurated. No tubercle bacilli found in smears from this pus; pus not injected into guinea pig. Tubercle bacilli in sputum. Patient had three inoculations with Koch's old tuberculin, and later this was changed to the new "T. R." There was no appreciable improvement in the local condition of the glands, and her pulmonary process became worse. She had five inoculations of the new tuberculin at ten-day intervals. She was discharged from the hospital after a stay of eight months, in a worse condition than at entrance.

CASE V. M. W., five years. Tuberculosis of the lumbar and low dorsal spine. Abscess. The child has been at the House of the Good Samaritan for two years. On entrance there was a large cold abscess which was opened. Tubercle bacilli were demonstrable in a smear from the pus and were grown on culture media. A few days after the abscess was opened he developed scarlet fever and was admitted to the Boston City Hospital. On his return he was treated a year in the wards with jackets. One year ago tuberculin treatment was commenced and as he had a secondary streptococcus infection of his sinus, he was given a streptococcus vaccine, made from his own organism, in addition to his tuberculin. His opsonic chart has been shown. There has been no local improvement of a permanent character. His sinus is still discharging and he has positive signs of phthisis and a suggestion of the development of an hypertrophic pulmonary osteo-arthropathy.

CASE VI. Master C., seven years. Tuberculosis of hip. Amyloid. Clinical diagnosis confirmed by histological examination after operation and by animal inoculation. In many ways this was a most remarkable case. The child came under observation at the Carney Hospital in less than a week after his first symptoms. Limp, pain and muscular spasm, accompanied by a high temperature, led to a diagnosis of acute osteomyelitis. At operation a small amount of pus was obtained coming from a necrotic focus in the neck of the femur. The process extended both up and down the femur and a secondary operation was performed for the removal of more of the dead bone. This was succeeded by an acute nephritis, which virtually became chronic. The spleen and liver were greatly enlarged and there was profuse suppuration from sinuses in the thigh. The boy was soon in such poor condition that it seemed as though he might die at any time. Inoculation with 1-1000 mgm. of tuberculin was commenced and repeated on the average of once in ten days. Improvement, though slow, has been steady since the injections were begun. There is much less discharge from the abscess, his color is better, and his abdominal distention is greatly diminished. The urine also shows less of the products of a chronic nephritis than it did some months ago. This patient had a mixed infection with staphylococcus and was given a staphylococcus vaccine along with the tuberculin. About twenty inoculations were administered. There has been a decided improvement in the general condition of this patient, a change which it seems fair to attribute to the administration of tuberculin. This case would not have been so suggestive were it not for the fact that at the same time we had another child in the hospital in almost the same condition.

CASE VII. F. S. This child is a boy of five and one-half years. He entered the House of the Good Samaritan in the fall of 1906. He had double tumor albus, both of which were suppurating. He was very pale and emaciated and had an enormous abdominal distention, part of which was caused by ascites and part by the size of his liver and spleen. There was a marked "caput medusæ." He had been having treatment under the best of conditions for the two years previous in the Children's, hospitals at Lowell and Bumkin's Islands, and failed to respond at all; in fact, had steadily grown worse. In desperation we commenced the administration of tuberculin, much against my better

judgment, as it seemed as though I should be subjecting the child to an unwarrantable discomfort. He began to improve after a very few injections and under no different constitutional treatment than he had been having for at least two years. He is not now recognizable as the same child who entered the hospital seven months ago. He is fat, of good color; his sinuses are nearly healed; his abdomen is soft and very little enlarged; the area of liver dullness has diminished, and though both spleen and liver are palpable, they are greatly diminished in size. Both knees are nearly completely ankylosed, but in very good position. He has had tuberculin administered with more or less regularity since his entrance. This case seems certainly to have benefited in a most extraordinary manner by the use of tuberculin.

CASE VIII. F. K., six years. Tuberculosis of both hip joints. Abscess. Erysipelas. Child was under treatment at various places for a fairly active tuberculous process in both hips. The left one suppurated, and during the course of the treatment the sinus became infected with streptococci, and she had quite a virulent erysipelas. A culture from her own sinus gave us the opportunity to make a streptococcus vaccine from her own organism, and this was administered along with her tuberculin injections. In this case the pus burrowed out below Poupart's ligament on the anterior surface of the thigh, and though opened freely, two or three times, under ether, refused to cease discharging. After the commencement of vaccine injections there was a very rapid diminution in the discharge until it finally ceased altogether. She was in the hospital about five and one-half months. Her chart has been shown. The progress of the tuberculous phase of her trouble was not affected by the use of tuberculin in any way.

CASE IX. A. McD., four and one-half years. Tumor albus. Abscess. Flexion and subluxation deformity of the knees. This child was transferred from the Convalescent Home of the Children's Hospital, where he had been under treatment for a year or more. His general condition was excellent. The knee itself had six or eight sinuses, from which there was moderate discharge. The joint was very much swollen, caused chiefly by bony thickening. A culture from his sinuses gave a pure culture of the staphylococcus. From this a vaccine was prepared and administered along with tuberculin during the fall and winter of 1906–7. During the past three months he has been at the seashore hospital at Marblehead, and his sinuses are reported closed. During this time he has not been having tuberculin. I could not observe any unusual response to treatment in this case.

CASE X. Miss P., twelve years. Tuberculosis of left hip. Abscess. This child entered the hospital with a very acute hip. She came from poor home surroundings and had had no adequate care. The thigh was flexed to a right angle with the body and traction would not overcome the spasm. Ether was given and the position corrected. Later a deep seated abscess appeared and was opened. From the time that I manipulated her in October, 1906, she commenced to fail. Tuberculin was administered before the manipulation and was continued through the fall and early winter without any effect; the patient became generally infected and died in March, 1907, of tuberculous meningitis. In this case I made the mistake of manipulating the hip-joint and precipitating into the child's general circulation more tuberculous toxins than she could neutralize. I very much question, in view of that fact, if it was proper to have given tuberculin. This catastrophe should not be cited as an argument against the employment of tuberculin, except in cases of a similar character.

CASE XI. Mr. B., forty-five years. Tuberculosis of left hip. Operation. Clinical diagnosis was confirmed by histological examination. Patient was a longshoreman, who had a rapidly developing ankylosis of his left hip, without shortening. An x-ray showed nothing suggestive of tuberculosis and it was regarded as a non-tuberculous, infectious process. Under ether the hip was manipulated. The motion gained was not preserved. Suspicion of tuberculosis again being aroused, he was given a diagnostic dose of tuberculin and had a sharp constitutional reaction but no exaggeration of local symptoms. An open operation was performed upon the hip later, and a number of spurs removed from the superior lip of the acetabulum and a small abscess was exposed in the region of the gluteal bursa. The pathological report from this was tuberculosis. Injections of tuberculin were commenced and continued through the summer, fall and early winter of 1906–7. The patient gradually failed, developed signs of phthisis, and died in the early spring of 1907. Again, in a case of this sort, the lesson it seems to me is that tuberculin is not to be administered, whatever other indications there may be upon estimates of the opsonic power of the patient's serum. Both this case and Case X were treated according to their opsonic indices.

In this series of 11 cases, therefore, we find 4 who were not benefited at all. Two were apparently most extraordinarily improved, and still another (case III) experienced an improvement which, considering the gravity of the symptoms, may fairly be classed as attributable, in large measure, to his vaccines. Two have died and a third is dying. It is an open question if another (case V) has not been made temporarily worse by the treatment. If we take out the 2 cases who have died, and it is fair to do this because they were cases in which the surgical measures employed may have imposed more of an infection upon the patients than it was reasonable to suppose any vaccination could take care of, there are only 2 cases left to speak positively in favor of the employment of tuberculin in the treatment of bone and joint disease. My experience, however, leads me to wish to give the method a longer trial, and with a more judicious selection of cases, I believe better results may be forthcoming.

If the outcome of vaccine treatment has not been brilliant in tuberculous lesions it has been even less so in the case of non-tuberculous lesions.

In chronic polyarthritis it would be the greatest possible boon if the opsonic test could be employed to discriminate between types of infection. If this could be accomplished with any degree of certainty, the next step, that of making a bacterial vaccine for purposes of treatment, should be a comparatively easy one.

In the earlier part of our experience with opsonic work there seemed to be considerable to suggest the possibility of a solution of the problems in the diagnosis and treatment of chronic polyarthritis. When, however, one regards the cases through a long perspective, there is not much to give encouragement at the present time. In acute infectious lesions of joints, such as gonorrheal arthritis, encouraging reports are coming from such reliable sources as the Johns Hopkins

Hospital and the Loomis Laboratory in New York, but the chronic problem seems to be a very different one.

Schüler, in Germany, has isolated from a very large proportion of the cases upon which he has been privileged to operate a bacillus which he regards as the specific organism of chronic progressive polyarthritis. Three years ago Fayerweather isolated from the knee-joint of a patient, upon whom I had operated at the Carney Hospital, an organism which he has described [11] and which Schüler [12] has declared from the description in Fayerweather's article to be identical with his bacillus.

The cultures of this organism had been preserved in the Tufts Pathological Laboratory, and we have been working with a vaccine which Dr. Leary has prepared from these cultures, in an attempt to diagnose and treat the type of polyarthritis with which, according to Schüler, this bacillus is constantly identified. All that can be said as a result of practically a year's experience with the application of the opsonic test for this bacillus is that we have been able to obtain a characteristic serum reaction in the blood of nearly all the patients who were possessed of the clinical signs of this type of polyarthritis. When it has come to treatment I think it is fair to say that there has been no considerable degree of improvement in any case, at least none which is not frequently seen in cases treated by other methods.

The fact that there has been such a uniformity in the opsonic findings in cases that are clinically of one type, together with this further observed fact, that when inoculated with a vaccine made from this organism they reacted locally, just as tubercular joints will react locally to too large an injection of tuberculin, it would seem that a lead had been given which it is worth while to follow.

The following cases are reported to show the kind of problems which have been attacked rather than to record favorable results of treatment:

Case XII. Mrs. L., forty years. Infectious polyarthritis. For five or six years the patient has been gradually becoming crippled in all of her principal joints and has been a great sufferer. With it all has come a considerable degree of neurasthenia. The joints are swollen, only slightly deformed, and possess very little motion. There is occasionally some redness over the phalangeal joints. Patient has been able to sit up in a chair, but walking has been impossible, except with the assistance of two persons to support her. All the possible sources of infection were investigated to make sure that there was no present infective focus. A blood culture was made and found to be negative. Cultures from the stools were also made, but the investigation along this line was not completed. The opsonic index to the staphylococcus aureus, the streptococcus, and Schüler's bacillus of villous arthritis was determined. The reports showed that the index was low, at various times, to each of these organisms, and vaccines were given for considerable periods, being graduated according to the response of the patient's serum to the inoculations. After approximately five months of such treatment there has been no appreciable improvement in the patient's local condition, which could be attributed to the vaccines. I think it is fair to assume, therefore, that the inoculation treatment in her case has been a failure.

Case XIII. Mr. F., forty-eight years. Chronic, progressive, infectious polyarthritis. Three years' duration. No present source of infection made out. Eighteen years ago had gonorrhea. Nearly all the joints in the body have become involved. No redness or other signs of acute inflammation. Marked deformities of the knees and limitation of motion in all the joints which have been involved. A blood culture was sterile. The patient's index was low to Schüler's organism and also to the streptococcus. No improvement attended the administration of vaccines from either of these organisms. During the treatment the patient has developed an iritis which has pretty completely impaired the vision in one of his eyes.

Case XIV. Mr. S., twenty-one years. Chronic infectious polyarthritis. After an exposure to dampness and cold one year before entrance to the Orthopedic Clinic of the Carney Hospital, the patient began to have swelling, stiffness and pain in both knees. This was rapidly succeeded by similar conditions in the wrists, fingers and feet. His index was low to Schüler's organism, but neither local nor constitutional condition was benefited at all by a few inoculations with a vaccine made from this organism.

Case XV. Mrs. S., thirty-eight years. Chronic infectious polyarthritis. Patient has had a chronic suppurating ear for several years. Following the birth of a child five years before, coming under vaccine treatment, she began to have trouble in several joints. The knees have become so badly flexed that she cannot straighten them completely. Her index was low to the streptococcus. The injection of a vaccine made from three strains of streptococci produced no alteration in the local condition, except that the pain was worse and there was greater stiffness immediately after the injections. The discharge from the ear practically ceased, but this may have been in consequence of careful treatment at the hands of an aurist.

Case XVI. Miss L., thirty-five years. Chronic progressive polyarthritis. The patient has been more or less constantly afflicted for five years with painful, stiff joints, particularly the knees, wrists, elbows and ankles. The symptoms were not very acute at the time she came under observation. She had had two very badly infected tonsils, and they were both removed; she had also had acute sinus inflammation. Her index was determined to be low to the streptococcus and also to Schüler's organism, and she was given faithfully for several months a vaccine made from a triple streptococcus culture. She also received a number of inoculations with a vaccine made from Schüler's organism. Neither of these produced any permanent effect. At times she, as well as several other patients, seemed to receive some temporary benefit from the inoculation.

Case XVII. Mr. W., forty-five years. Infectious polyarthritis. For four or five years he has been gradually becoming stiffened in the joints of his knees and hands. One year ago he had an attack of pneumonia, during which the swelling disappeared entirely from his joints, and when he commenced to get about during convalescence, he felt that his arthritis had entirely disappeared. This immunity from former joint symptoms was only temporary, for within a few weeks all his old troubles had recurred, and since that time the knees had flexed to such a degree that walking was painful and difficult. The patient's index was taken for the staphylococcus, streptococcus, pneumococcus, colon bacillus, and Schüler's bacillus. His index was low to the pneumococcus and Schüler's bacillus. Vaccines

[11] R. Fayerweather: Am. Jour. Med. Sc., Dec., 1905.
[12] Schüler: Am. Jour. Med. Sc., Aug., 1906.

from these two organisms were repeatedly given, guided by the opsonic index, and no material improvement occurred, which could not be attributed to local and constitutional treatment coincidently carried out.

CASE XVIII. Mr. S., fifty-two years. Subacute phlegmon. Two years ago, while in Egypt, had a very acute phlegmon of the cheek, for which he was operated upon in Cairo, and had at the same time very large and often repeated inoculations of antistreptococcic serum. Since then, in various parts of his body, never in any joint, but usually in close proximity to some large articulation, he has had more or less subacute phlegmons. One of these, close to the elbow joint, was incised and a pure culture of the staphylococcus aureus was obtained. From this culture a vaccine was made and the patient was given several inoculations of this vaccine without any appreciable benefit.

The next 2 patients had intermittent hydrops.

CASE XIX. Mr. R., thirty-six years. Intermittent hydrops. Psoriasis. For seven years has had at irregular intervals an intermittent swelling in both knees and both ankles. Associated with this condition has been a very general psoriasis. When, as has happened on several occasions, he has had freedom from joint symptoms for six months at a time, he has also been entirely free from psoriasis. The knees have caused him the greatest inconvenience. The right one has been the more swollen and has had a five-day interval between attacks. The cycle for the ankles was not as clearly defined and he had never taken the trouble to determine it. The capsular swelling in the knees wholly disappeared. The right knee-joint was subjected to an arthrotomy with the hope that the cycle might be broken up. A culture taken from the interior of the joint gave the staphylococcus, which seemed a peculiar bacteriologic finding, but a vaccine was made from the culture and was regularly administered. For three months the operated knee showed no signs of an intermittent swelling. The left knee during this period was less inclined to swell, but did so to some extent. At the end of this interval the right (operated) knee returned to its cyclic distention, though the enlargement has not been as great as before. Observations upon the opsonic index at first showed that it was low to the staphylococcus, but later on the streptococcus seemed to be the organism which showed a low index, and accordingly a streptococcus vaccine was substituted, but without any alteration in progress of the trouble.

CASE XX. Miss S., thirty years. Intermittent hydrops. Both knees have swollen alternately every seven days for over two years. Two days were required for the swelling to attain its maximum and recede. The swelling caused a little pain for a few hours, but chiefly inconvenience from the enlargement. Her serum was tested and found to be low to the streptococcus. A vaccine was injected regularly for some time, but not carefully watched with opsonic tests. The patient has been taking Fowler's solution alternating with quinine during this entire period. There have been two intervals of two weeks each when there was no appreciable swelling in either joint, but this has occurred before under other treatment and no treatment. The amount of swelling is decidedly less, though except for the two intervals cited, there has been no intermission of the regular cycle.

Discouraging as these cases are, looked at from the clinical point of view, it must be remembered that we have been applying a new method, the shortcomings of which are not at present wholly understood. Circumstances have sometimes existed making it impossible that some of the conditions imposed by laboratory investigators could be carried out. It may be that cases have been treated with vaccines made from organisms having no possible kinship to the organisms originally present in the patient, though the opsonic findings have pointed that way. Again it may be possible that some of the conditions treated were not originally caused by an infective agent. These and many other obstacles stand in the way of drawing conclusions from the results of the first year's clinical experience. A good many more cases were treated and tested than have been recorded here, but those selected for report were chosen because they covered the types of cases most satisfactorily. It would have been possible to select a group, perhaps an equally large one, where the conformity of the opsonic and clinical findings would have been entirely favorable to this new method of study. So in the matter of treatment, typical opsonic charts might have been exhibited corresponding to remarkable degrees of clinical improvement. The writer believes the danger of expecting too much from an untried method is greater than that of expecting too little, and is desirous of encouraging the continuance of trials now going on in the laboratory provided they can be checked by unbiased clinical observation.

DISCUSSION.

DR. L. S. MEDALIA, of Boston: I wish to say that some of the cases that Dr. Painter has mentioned have not been under treatment since the first of February. There are a few cases at the Good Samaritan which have been treated up to date, but those at the Carney Hospital have not been followed up since February 1.

I would emphasize the fact that this treatment has to be carefully and energetically carried out, for the conclusions drawn from those not followed up properly have been unsatisfactory.

THE SERUM TREATMENT OF EXOPHTHALMIC GOITER. A REVIEW OF THE LITERATURE.

BY FRANK S. BULKELEY, M.D., AYER, MASS.

UPON looking over the available literature on exophthalmic goiter, one is at once struck by the fact that drugs having very different actions are, or have been said to be, of benefit. Much of the treatment has been purely symptomatic, perhaps necessarily so. It is hard to see how many of the drugs used could have any influence on the causative factor in the trouble, and their main, if not only, value seems to have been in palliating certain symptoms. This leads us to ascribe the reported cures to general hygiene and the tendency to spontaneous recovery that certain cases show. In a general way such drugs may be divided into four classes: "Nerve sedatives," "vascular sedatives" and cardiac stimulants,

gastro-intestinal antiseptics and laxatives, and general tonics, so-called. Many of the results seem, in the light of more recent investigations, mere coincidence, and the fact that spontaneous recovery occurs at times lends strength to this view. Among the various drugs used, belladonna, ergot, intestinal antiseptics and laxatives of various sorts, strophanthus, digitalis, phosphorus, sodium salicylate, bromides, iron and quinine hydrobromate are, perhaps, the most generally used. Forchheimer speaks very highly of the last named drug, and many reports favorable to its use are on record.

The first signs of an attempt at a specific treatment were seen in the use of milk and blood serum from thyroidectomized animals. This has been followed by an attempt to obtain a specific antitoxin by Rogers and Beebe of New York. They report 90 cases, of which 23 were pronounced cured, 52 improved, 11 were not benefited, and 4 died. The cases were of all grades and at all stages. Some of those reported as benefited may later prove to be cured, and some of those not benefited may show improvement. The originators of the serum state that the chronic toxic cases are the most resistant. The dosage and possible limitations of the serum do not seem to be generally understood, and for further details one should consult the original articles.[24] Their serum is a very different thing from the sera prepared by the various manufacturers, and calls for separate consideration. I have had no experience with it, and shall not include it in this review. I have collected the following cases from the available literature:

Enriques.[1] Reports in 1895. Nine cases treated with serum from a thyroidectomized dog. Exophthalmos and all other symptoms relieved. A further report in 1903 says end results are disappointing.

Lanz.[2] Six cases treated with milk from a thyroidectomized goat. One case treated two weeks. Pulse before, 90; after, 70. Goiter less, and general symptoms much improved. One case treated nine weeks. Pulse before, 134; after, 88. Goiter less and all symptoms benefited. One case treated three months. Pulse before, 150; after, 80. Goiter less. Feels completely cured. One case treated three months. Pulse before, 130; after, 80. All symptoms benefited. Previously bedridden, now able to work. One case treated three months. Pulse before, 130; after, 60. Later went through pregnancy and labor without trouble. One case treated three months with great improvement.

Burghart.[3] Three cases treated with the blood of a myxedema patient. Gain in weight and remission of all symptoms.

Moebius.[4] Two cases treated with Moebius' serum. Marked alleviation of symptoms in both cases.

Schultes.[5] One case of three years' duration treated with Moebius' serum for six weeks. Pulse before, 240; after, 90. General and mental symptoms much improved.

Goebel.[6] One case of ten years' duration treated a few weeks with milk from a thyroidectomized goat. Previously bedridden, now able to walk a mile without fatigue.

Kuhneman.[7] One case of six weeks' duration treated with rodagen for one month. Pulse before, 140, after, 90. All symptoms gone, gained twelve pounds. Reported later as completely cured.

Murray.[8] Two cases treated with Murray's serum. Moderately good results in both cases but is not sure it was due to serum.

Thirniger.[9] Two cases treated with Moebius' serum. Both benefited. One, an acute case of five days' duration, apparently saved from death by two weeks' treatment.

Hempel.[10] One case of six weeks' duration treated with Moebius' serum for one month. Pulse before, 180; after, 90. Total of 90 G. serum used. Patient satisfied with her condition four months after treatment was stopped.

Moussu.[11] One case treated with parathyroids of a cow. Gained, but died later of tuberculosis.

Macullum.[12] One case treated with parathyroids of a cow with no result.

Christian. Eighteen cases treated with thyroidectin. All considerably benefited.

Kuh.[14] Ten cases treated with thyroidectin, and one with Moebius' serum. "An excellent palliative but am not certain of permanency of results." All symptoms rapidly improved. In one severe case patient has had no symptoms for two and a half years.

Mix.[14] Two cases treated for a long time with small doses, Moebius' serum. Both are at work with a complete disappearance of all symptoms.

Vanderhoof.[15] Two cases treated two months with thyroidectin. One able to work as hard as ever without trouble. One much improved, but not able to work at time of report.

Waterman.[16] Five cases treated with Moebius' serum. Two cured, free from all symptoms for six and eighteen months. Two benefited, and one not improved.

Rydel.[17] Four cases treated with rodagen with benefit, but is not sure it is due to serum.

Siegel and Ewald.[18] Four cases treated with rodagen with no result.

Adams.[19] One case of three years' duration treated with Moebius' serum for one month. Previously bedridden, but has been at work six months without symptoms.

Kirnberger.[20] Two cases treated with rodagen with disappearance of all symptoms and general improvement.

Peters.[21] One case treated with Moebius' serum with good results.

E. Von Leyden.[22] Three cases treated with Moebius' serum. One case of three years' duration. Pulse before, 96; after, 80. Marked general improvement. One case of two years' duration feels much better. One case cured by eighteen months' treatment.

Sainton. Three cases treated with blood of a thyroidectomized sheep. One case treated eight months. Pulse before, 115; after, 80. "Patient transformed into new and healthy woman."

1	Bulkeley, 1907	About 8 months	About 4 months with serum	Moebius' thyroidectin	100 to 140	70 to 85	Apparently aggravated		1		Patient greatly improved, but quite certain it is not due to sera, as they seemed to aggravate symptoms.
86		Totals,						80	6		Sixteen possible cures judging from data given.
				PARATHYROIDS.							
1	Moussu, 1904							1			Gained, but died later of tuberculosis.
1	Macullum, 1905								1		
4	Walsh, 1905							2	2		One severe case not benefited, 2 mild cases apparently benefited, 1 severe case aggravated. Not certain there was no thyroid admixture.

One case treated six months. Pulse before, 120; after, 100. Great improvement, but has to continue serum. One case of three years' duration treated three weeks. Pulse before, 134; after, 84. "Cured but has to continue serum."

Walsh.[23] Four cases treated with parathyroids of a cow. In two mild cases seemed to have a good effect. One severe case not benefited, and symptoms aggravated in one case. Not certain that substance used was free from thyroid admixture.

Billings.[20] Reports 12 cases treated with thyroidectin with varying results, but in no case did he secure the favorable results recorded elsewhere. In 1 case Moebius' serum and quinine hydrobromate were used, with resulting steady and continuous improvement.

In the majority of the cases reported not enough detail is given to allow one to judge of the probability of cure, or of the permanency of results. One case reported by Lanz was able to go through pregnancy and labor without trouble. In view of the tendency to increased thyroid secretion in pregnancy, this may, perhaps, be called a cure, although we must admit that such a tendency is not constant. Lanz reports 3 other cases that seem possible cures. Schultes, Goebel and Kuhneman report cases that might be considered permanently cured. One of Hempel's patients was satisfied with her condition four months after treatment was stopped. Kuh reports that one patient is free from symptoms two and a half years after stopping treatment. Mix, 2 possible cures. Waterman, 2 cures of six and eighteen months' duration. Sainton, 1 case cured. Von Leyden, a case cured by eighteen months' treatment, etc. Nearly all the writers quoted report improvement, and we may, perhaps, be warranted in accepting the statement made by Elsner and Wiseman [25] that the palliative action of the serum seems certain and a cure may be possible. They say, "Improvement usually begins within seven days, and that if there is no improvement in three or four weeks the chances are against ultimate benefit. Tachycardia, tremor and precordial distress show the greatest improvement. Cases without marked goiter, with slight tremor and exophthalmos yield most readily. There usually is an increase in weight. Continued use of the serum may be necessary." My experience with the serum is too limited to allow me to venture a decided statement, but I cannot agree that the palliative action of the serum is certain, however probable it may seem. Osborne [26] states that there is no doubt that the proper treatment of exophthalmic goiter is by antithyroid preparations, but he is not certain whether the treatment can be pushed or prolonged with safety. The assertion has been made that the sera occupy the same relation to exophthalmic goiter that thyroid extract does to myxedema, but such a statement can hardly be accepted on the evidence at hand. It seems as if the writers used the term cured in a very different way. Some do not report cure where it seems probable; others claim it where only palliation of symptoms seems certain. It is desirable that a cure in this condition be more exactly defined.

A contrast of the different sera offers little of value. Two observers report 4 cases in which rodagen was useless, although other reports are favorable to it. The other sera seem to have given uniformly good palliative effects. Practically all the writers quoted report improvement, far too many to have it seem coincidence. It seems as if the treatment is at least worthy of a trial in every case. An estimate of the cures from the data given is very difficult, and I shall attempt no such estimate.

I have made use of the sera in one case with very doubtful results. In this case, goiter was slight or absent, tachycardia and tremor well marked, exophthalmos absent, and the other symptoms those usual in such cases. The thyroid was palpable and visible, but at the same time was no larger than is common in many healthy women. Thyroidectin was used in increasing doses. For a time it seemed to be of some benefit but this effect was soon lost, in fact it seemed to aggravate the symptoms. Later, Moebius' serum was tried with practically the same results. Quinine hydrobromate was used for about five months, in doses just under that necessary to produce cinchonism. It seemed to give positive results. Although the amount of bromine in this preparation is small, a daily dosage of 16 gr. was sufficient to cause a well marked bromic acne in this case. Because of the small amount of bromine in the drug it did not seem probable that the bromide action could be the main factor giving relief. For this reason quinine valerianate was substituted, and while it was used for only a short time, the results obtained seemed to equal those from the hydrobromate. The bromic acne produced soon disappeared after the drug was stopped. At present, while it is too early to make a positive statement of results, the patient has gained in weight, has made little or no complaint of tachycardia for six months, and has little or no tremor. Her main complaint is occasional undue fatigue from very ordinary causes, which seems to be growing less marked. Some flatulency, and a tendency to insomnia and anorexia are about the only other symptoms left, and she has been subject to the two latter ones for years. She is able to go about a great deal with no trouble, and does all her household work. Pulse records taken at random during the past six months have been from 70 to 85, although it is possible that higher records could have been obtained. During the height of the trouble a record of 100 was the rule, and 120 to 140 was no exception. She has had no medicine for about six months. Rogers and Beebe state that some of their cases showed no improvement at the usual period for it to commence, but that it came on after a long interval. It may be that this was the case in the present instance, but the nature of the two remedies and their probable mode of action are so different that it seems improbable. It also seems im-

possible to say that any delayed improvement was not due to a tendency to spontaneous recovery, or to some other means of treatment. I certainly can trace no benefit directly to the serum in this case.

In arranging the cases in tabular form I have included all cases under the terms "benefited," or "not benefited." The probability, or otherwise, of cure, I leave to the individual reader to determine. Thirteen cases reported by Billings are not included in the summary as the details given are very scanty, and no distinct statement of failure to benefit, or of improvement is made.

The tabulated cases appear on pages 28 and 29.

SYPHILIS AND GONORRHEA IN INTERNAL MEDICINE. *

BY ROBERT N. WILLSON, M.D., PHILADELPHIA.

Of all the economic problems with which this and other nations must deal, none exceeds in difficulty that of venereal disease. Syphilis and gonorrhea have been reaching out for the vitals of more than one race, and have laid hands heavily on the civilized world. Venereal disease forms a serious social, as well as medical, dilemma. To the necessity of applying itself to this dilemma, the public is just opening its eyes.

One needs to look back only a few years to recall a period in which venereal disease was treated as a matter of course, and often as a half joke, by the general practitioner, and if not by him by the druggist, and at a still earlier time, by the barber-at-large. The profession has grown up, as it were, with venereal disease in its midst, unwillingly conscious of the presence of an unwelcome companion, and yet finding its acquaintance more and more intimately thrust upon it as time has flown. The doctor has known syphilis and gonorrhea as the dog knows his enemy the flea, but no more intelligently. Along with the rest of humanity he classed these diseases as necessary evils to be borne with stoicism and to be disregarded when possible, because too closely bound up with the recognized pleasure of life to admit of a change. The youngest of us can remember the advice of our medical seniors to enjoy our wild oats, because only in such a way could the experience necessary to a doctor be gained. No word was uttered regarding injuries that might accrue to the individual and his home.

Within a few years the medical profession has been learning that syphilis and gonorrhea are factors to be seriously reckoned with. The possibility of the influence of syphilis is considered in every diagnosis, and in the planning of every treatment. Its earmarks stand out upon the highborn and the lowly, the king and his subject, from the grandfather to the third generation. The doctor is to-day hurrying to stem a tide which years ago might have been turned with a finger. He pays no small price for this privilege of serving the people, as is seen in the record of professional accidents that annually result in the syphilization of not a few members of his calling. If there were no other incentive, the danger to which he is daily exposed would commit him to a position in the front line of the battle, now to be waged against a common enemy. The doctor is trusted by the public to a degree that is shared by no other public servant. The laity must simply remind him and keep him faithful to this trust by its interest and encouragement. In one form or another syphilis or gonorrhea enters at some time nearly every home. Their ultimate consequences account for a morbidity and mortality that will exceed that of any given class of disease. The plain physician, the general practitioner, alone knows the full sorrow of venereal infection in the home. He has not realized that the public has for some time been ready for the facts which he has kept in his bosom. Medical literature is full of the material that will rouse the public to action. The people stand at the doctor's door, with hand at ear. What will conservatism and professional ethics allow him to say?

A hurried glance at the literature of syphilis and gonorrhea published during the period 1903 to 1906 inclusive yields the following interesting facts. Four hundred and seventy-five articles have appeared in the leading medical journals, dealing with syphilis alone. The average number of cases of syphilis reported in this series was ten per article; but many included the reports of from 500 to 1,000, and few recorded less than 5. As each instance of syphilitic infection represented at least one other as its cause, this library deals with not less than 5,000 public reports of cases of syphilis, and more much likely 50,000, if the full count were made. During the same period 176 articles appeared upon gonorrhea, a disease which has been discussed, until there is little to say beyond the fact that the profession realizes with each new year how little real knowledge it has upon the subject. The danger is the only settled and established factor, other than the causal germ. Syphilis is at most times a purely medical condition. Only when the internal organs are seriously involved does the syphilitic come for a moment under the surgeon's care. Gonorrhea, on the other hand, has been considered

*Read before the Pennsylvania Society for the Prevention of Social Disease, March, 1907.

almost exclusively a surgical condition; and only the second glance of one who studies the ramifications of the disease determines how far into pure medicine it may wind its way.

Let us consider, very briefly, these two conditions from the standpoint of internal medicine and the public.

SYPHILIS.

What medical conditions grow out of, and what is the *natural* outcome of, this disease? Probably if every case of syphilis were isolated and treated by judicious medication and overfeeding in the fresh air, after the manner of tuberculosis, the disease could be stamped out within a few generations. Comparatively few cases are treated thoroughly, and many not at all; and, worst of all, isolation seems neither practicable nor promising of the best results. Prevention seems to be the only satisfactory measure. Every specialist begotten by the medical profession is supplied with material for study. Arteries become hard and lose their elastic and muscular coats. The brain, as a consequence of the arterial calcification, either receives too little blood supply, or a vessel ruptures, and the overamount produces pressure and an apoplexy. The internal organs are sclerosed, some break down into gummata, sclerosis takes place in the liver and spleen, chronic Bright's disease, gastric tumor (gumma), may all be occasional occurrences in the course of syphilis.

The dermatologist notes every variety of skin eruption from a simple erythema to a tubercular syphilide. The orthopedist sees Pott's disease as typical as that caused by tuberculosis; also rickets, and its consequences, and all forms of bone disease.

The ophthalmologist treats keratitis, iritis, choroiditis, optic nerve disease, disease of the lachrymal sac and even the primary sore. It may be interesting to digress long enough to quote in this connection a case reported in 1905 by de la Roche. A young woman of good family consulted an ophthalmologist for a sore upon her eye. He found a typical chancre on her left lower lid, and later observed the symptoms of constitutional syphilis. The woman was a bride who, on her wedding trip, developed a sty. A chambermaid offered to cure it by rubbing, and used in the process her finger, moistened with saliva. The result was the syphilitic infection of a clean woman, and the establishment of a new focus for the spread of the disease.

Reber noted the fact in 1904 that such a primary sore is by no means infrequent, as the result of the application of the tongue to the eye to remove a foreign body, — a common practice among the lower classes. Blaschko reports the cases of twelve doctors seen in ten years, infected in their professional work with syphilis, most of them upon the hand or finger.

The specialist on the stomach will tell you that syphilis may cause any gastric picture, from that of round ulcer to carcinoma. Hayem reports four typical cases of tertiary syphilis of the stomach as follows: Case I simulated a gastric ulcer to such an extent that this diagnosis was made. Case II seemed to be one of benign pyloric stenosis. Case III a tumor in or near the pylorus. Case IV a deceptive simulation of cancerous stenosis. One of these patients was sixty years old, and looked as if he were in cancerous cachexia; but gave a history of chancre forty years before, and recovered on antispecific treatment.

Margulies describes a case of kidney tumor in a woman of twenty-six years, which when opened up was manifestly of syphilitic origin. Wagner cites 14 cases of syphilitic Bright's disease. Quincke notes three interesting instances of abdominal syphilis, one showing a series of gummatous indurations in the cystic duct, and in the head of the pancreas; a second, presenting a gummatous mass pressing on the portal vein and biliary ducts; and, lastly, a mesenteric gumma that pressed upon the stomach, causing dilatation of that organ and stagnation of its contents.

Trinkler reports a case of syphilitic tumor of the pancreas, diagnosed and operated upon as probable cholecystitis.

Klemperer describes a number of cases of syphilitic disease of the liver. Riedel reports several cases of syphilis of the gall bladder, all operative, one of them a physician.

König cites numerous instances of syphilitic tumor of the liver. Von Düring deals with syphilitic aortitis, and states that syphilis has been demonstrated in 56% to 85% of the cases of aortic aneurysm on record. Aneurysm in youth (below fifty years) is nearly always the result of syphilis.

Goldfrank reports a case of multiple gummata of the heart with sudden death. Jones states that in his experience a syphilitic history more frequently precedes valvular lesions of the heart than does rheumatism.

Locomotor ataxia is more and more convincingly ascribed to syphilitic influence. Preobrazhensky reports the case of a child of twelve years with tabes. The mother was syphilitic and developed tabes at the same time with her son. Erb records 400 cases, of which 45% gave an unmistakable history of syphilis or chancre, and in the remainder syphilitic antecedents were probable in all but 2.8%. Erb states that of 600 educated men of the upper classes studied by him, 43.3% were absolutely free from venereal disease. Only 50% of the 600 had had gonorrhea! Adrian describes many cases of tabes in syphilis. Fournier gives his record of 112 cases of general paralysis, in which the date of the primary syphilitic sore is known. All belonged to the well-to-do class. The shortest interval before the onset of paralysis was three years; in the great majority it was ten years. In 223 cases of cerebral syphilis with hemiplegic onset, fully two thirds developed within five years of the primary infection. Nearly all gave a history of insufficient or no treatment. All authorities emphasize the lesson that every case of syphilis, especially those which are clinically light, should be treated energetically and persistently, and be watched for the first sign of

tabes; then again energetically treated as before. Also that every case of tabes should be studied for syphilis.

Pritchard cites cases of intracranial syphilis. Peter gives others with disease of the brain and cord. We have ourselves recently studied four cases of cerebrospinal syphilis, two of these in educated, well-to-do men.

Mettler writes of the neuroses due to syphilis; he has also reported cases of syphilitic chorea.

Muravieff and (elsewhere) Gowers describe syphilis of the central nervous system. Finally may be mentioned the fact that syphilis not infrequently involves the peripheral nerves, resulting in neuralgias, polyneuritis, or root neuritis. Usually the trigeminus is involved, and in company with it either the optic, facial, or oculomotor, or other of the cranial nerves. There seems, moreover, to be no doubt that syphilis predisposes to tuberculosis. Fraenkel, Klebs, Beck and many others have cited series of cases that support this view, which has been amply borne out by our own experience upon the wards of the Philadelphia Hospital.

Douty gives expression to the general opinion that 30% of the tuberculous are syphilitic.

Jones believes that the high mortality among the negroes is due to the syphilization of the race with tuberculosis superimposed. Few, if any, are cured of tuberculosis, even when under favorable surroundings.

Time and space remain for only a word regarding hereditary syphilis, the almost certain outcome of syphilitic parentage. Near Stockholm a sanatorium has been built for children suffering from congenital syphilis, in which, under proper care, many have been enabled to survive. As a rule the syphilitic child dies very early. If it survives it often is rachitic, often shows active bone affections, sometimes Hutchinson's triad of syphilitic teeth, keratitis and centrally impaired hearing. Sometimes the syphilis remains latent for months and even for years before manifesting its presence.

Lannelongue claims that Parrot's disease in the young and Paget's disease in adults and in the aged are both syphilis.

A number of writers, among them Etcheverer, cite cases that appear to suggest a predisposing relation between a syphilitic soil and cancer. He notes 13 cases of cancer following leucoplasia; and a still larger number that developed in syphilitic lesions of the mouth. He cites a number of cases reported by others.

Treatment need only be referred to at sufficient length to state that the tendency seems to be to follow the intensive, hypodermic method, injecting mercurial solutions deep into the gluteal muscle. With the discovery of the spirocheta pallida as the probable cause of syphilis Schaudinn has given us both welcome news and an additional incentive to treat the individual case intelligently and well. Not only have we in our possession the possible key to an effective cure, but the urgency of haste, now that we know the spirocheta to be present and virulent even in the tertiary stage.

Doutrelepont published four cases of tertiary syphilis, in each of which he found the spirocheta pallida. Rille and Vockerodt also found the organism in extragenital lesions nine years after infection. Many similar cases are already on record.

Metchnikoff, Neisser and others are now at work upon a series of inoculation experiments upon the various monkey genera. The transference of the disease to these animals is without difficulty and the infection has repeatedly been passed from one monkey to another.

The next advance will be toward, if not to, an immune serum. We have dwelt upon syphilis almost to the exclusion of gonorrhea for a distinct purpose, namely, that it might appear clear to every one that syphilis is a disease which insinuates itself into the lives of physicians and laymen from all sides, openly and in disguise, and in a wide distribution that will require years of effort and patience to conquer. Yet the task can be accomplished just as certainly as with smallpox, and as it will be with tuberculosis. A long step toward this end will have been taken in the discovery of the cause of the disease. An equally marked advance will be the arming of the people with the facts.

GONORRHEA.

A new teaching is also required for gonorrhea, to the effect that it is not merely a local infection of the urethra, but that in every case it is a systemic infection of the blood and lymphatic glands. In most cases, to be sure, the disease manifests its symptoms locally, either in the urethra, the vagina, the uterus, the eye, the rectum, or, much more rarely, the mouth, the nose, the ear, and other portions of the body.

Bull cites five instances of iridochoroiditis. Apetz cites one of gonorrheal ophthalmia, an autoinfection of the eye after six years of latency in the urethra. Kimball reports 8 cases of gonococcus pyemia in infants. Larson describes 2 cases of gonococcus abscess of the sternoclavicular articulation. McColgan and Cooper cite many instances of gonorrheal metastasis and pyemia. K. Flügel recites a series of 56 children with gonorrheal vulvo-vaginitis, in 20% of whom rectal infection had occurred.

L. Emmett Holt urges the stringent isolation and care of gonorrheal patients in children's institutions. In all its forms gonorrheal infection is difficult of control, but in an institution for children it is a scourge. Gonorrheal vaginitis is very frequent in such buildings, and only strict isolation and scrupulous care will prevent or subdue an epidemic.

Lowenburg relates the case of a four-year-old child who infected himself probably by handling the rags and clothes from the refuse boxes. There are not a few instances on record of infection in tiny children as the result of coitus with other children or with adults.

Helman reports a case of multiple periarthritis (gonorrheal) in a child inoculated through a skin wound; Krause notes two cases of gonococcus

sepsis, the gonococcus being obtained from the blood of the patient during life; Powers reports one of diffuse gonococcus infection of the entire upper extremity; and Salomon, a case with gonorrheal cutaneous ulcers. Gonorrheal ophthalmia is responsible for from 10% to 25% of the inmates of our blind asylums. The gonococcus surgery of the abdomen includes from 10% to 90% of all the pelvic suppurations in women, the figure varying with the operator. In the male a large part of the surgery of the genito-urinary tract can be traced to the gonococcus as a cause.

There remains simply the statement that the aorta, the smaller vessels, and the heart itself, are all subject to attack by the gonococcus. Eisendrath feels certain from his experience that urethral gonorrhea exerts a distinct influence predisposing the genito-urinary tract to tuberculosis. In both male and female, he says, gonorrhea prepares the soil for a later invasion by the tubercle bacillus.

In the face of the foregoing facts, would it not seem likely that when the public is thoroughly informed it will speedily alter the social conditions that led Joseph Taber Johnson to say only a year ago that "90% of all men acquire the disease." Even if we take exception to his large figure, as some of us will be inclined to do, the minimal percentage persists above 50%, and the consequent harm to the people in sickly women and incapacitated men, and in sterile men and women is sufficiently striking to engage the attention of those who are disposed to protect themselves and their neighbors. Neither syphilis nor gonorrhea is a desirable public asset. In due time, through organic disease, through sterility of both sexes, or through fetal death, they will decimate the hardiest race. Though both are curable under favorable conditions, many unnecessary infections may, and often do, take place while one is being cured. Many cases fail of cure. The ultimate result at such a rate is a retrograde rather than an advance. There is only one radical cure, and only one method of procedure will avail. If the medical profession will inform the laity fully and freely as to the facts in the case, the work will be in the hands of the people from that time forward. There is little doubt that they will rise to the occasion. Their co-operation is indispensable to their own salvation and nothing short of thorough accomplishment should be their aim.

ANATOMIC AND PHYSIOLOGIC REST OF THE PERITONEUM IN PERITONITIS.

BY BYRON ROBINSON, B.S., M.D., CHICAGO.

SINCE I was a pupil of the late Mr. Lawson Tait, one of the greatest surgical geniuses of his day, I have studied and practiced the subject of *anatomic and physiologic rest* of the abdominal viscera, for fifteen years. Mr. Tait was profoundly suggestive, teaching rather by example and practice than by theory. I learned from the brainy Tait the inestimable value of anatomic rest and physiologic rest in abdominal disease, *i. e.*, practically anatomic and physiologic rest of the *peritoneum.*

Anatomic rest is maximum quietude of skeletal or voluntary muscles. A voluntary, motionless state is secured by rest in bed, not rising for defecation or urination.

Physiologic rest is minimum visceral function. Minimum visceral function is controlled by means of fluid, food, mental quietude and therapeusis. The essential factor in minimum visceral function is peristalsis. Visceral peristalsis is an executor of pain and a distributor of sepsis. The method of treatment for abdominal pain by anatomic and physiologic rest was especially advocated by the distinguished English physician, Wilkes, in 1865 (living at present), continued by the famous American, Alonzo Clark (1807–1887), by the "opium splint," and established forever in 1888 by one of the greatest surgical geniuses of his age — Lawson Tait (1845–1900). Mr. Tait did not secure his success from so-called antiseptic surgery, nor from even present methods of aseptic surgery, for I have watched him do successful abdominal sections on returning from his yachting expeditions, where he delighted to be his own cook, with anything but aseptic hands, and by washing them in soap and water two minutes or less, was ready to do the section.

Tait's success lay in anatomic and physiologic rest with thorough visceral drainage, especially of the tractus intestinalis. He used to remark to his few pupils that the patient should have the bowels so thoroughly evacuated that the intestines were like slippery ribbons when the abdomen was opened. When the intestines are contracted to the shape of slippery ribbons they are in a state of physiologic rest. Besides, Tait kept the bowels in a state of physiologic rest by allowing no fluid or food per mouth for forty-eight hours — a cruel method — after the section. Practically, the patient was without food for four days so far as any action on the bowels was concerned.

Anatomic rest was secured by rest in bed — quiet bones and muscles. On the third day, Mr. Tait again drained the tractus intestinalis with magnesium sulphate and mild chloride. This gave the bowels another physiologic rest, after the visceral drainage. For some fifteen years, I have been following the method of anatomic and physiologic rest in the inflammatory and operative diseases of the abdomen. I am induced to write this on account of the slight attention paid to the subject of anatomic and physiologic rest by so many general practitioners and general surgeons.

First and foremost, the most striking success in anatomic and physiologic rest is shown in septic abortions. Even as short a time as ten years ago, it was a general treatment in some hospitals in septic abortion to curette vigorously, irrigate and pack the uterus immediately on arrival at the hospital and follow this by vigorous catharsis. I learned fifteen years ago from a considerable practice in gynecology and obstetrics, that

it was a very fatal practice. In fact, when at that time I saw a case of abortion with temperature 105°, pulse 130 and severe tympanitis, I generally considered the prognosis was fatal with the then active treatment. For the past dozen years in abortion cases I have assumed the treatment I learned from Lawson Tait, *i. e.*, that of anatomic and physiologic rest. When the abortion patient arrived at the hospital, septic, with a temperature of 105°, pulse 120 to 140, with severe tympanites, she is placed on her back in bed, she is not allowed to rise for stool or urination (anatomic rest). No food or fluid is allowed per mouth; she is given a hypodermic of morphine for pain, and warm normal salt solution is injected into the rectum to abate thirst (physiologic rest). Her friends fight against this alleged cruel and unusual punishment, but the hospital should get control of the patients by soon parting with the friends. It is astonishing what a day and a night's anatomic and physiologic rest will do for a septic aborted patient. She soon becomes easier under rest. The small doses of opium aid to check the pain which is wild peristalsis. The tympanites subside. In a few days one finds the peritoneal exudate still there, but in a couple of weeks, if abscess formation does not occur, they begin to subside, absorb. Put the intestines at rest and they will not distribute the sepsis over the abdominal cavity by wild and irregular peristalsis. Under anatomic and physiologic rest, seldom does one lose an abortion patient.

In the second ten years of my practice I have saved double the number of septic abortions by means of anatomic and physiologic rest, in comparison to the so-called active treatment.

I am aware of no septic infectious process where the anatomic and physiologic rest method will demonstrate its utility as well as in septic abortions. Again, for about ten years, an able surgeon, whom I would meet almost daily, has tried to convince me that hot, moist compresses saved him from amputating many limbs. Hot, moist compresses with him are a hobby, and I must say that he saves many terribly septic limbs and fingers. However, I think this good surgeon is mistaking hot, moist compresses for the favorable therapeusis, — anatomic and physiologic rest. When a septic limb is put to anatomic rest, the bone is immobile. The muscles lie quietly, no contractions and relaxations impel or force the lymph stream proximalward, conveying sepsis with it. The blood stream is physiologically quiet, moving at a minimum rate. In short, the sepsis in the infected limb is being circumscribed by anatomic and physiologic rest, and not by hot and moist dressings. He also claims that the hot, moist dressings must be antiseptic, as bichloride of mercury or alcohol. I have argued with this surgeon that it was the anatomic and physiologic rest that produces the favorable effect in the cases which he thought was due to hot, moist dressings. In perityphlitis, the most treacherous and dangerous of abdominal diseases, — dangerous because it kills, and treacherous because its capricious course cannot be prognosed, — anatomic and physiologic rest is equally favorable; but it fails in some cases where the sepsis has been excessively distributed by enteronic peristalsis, and therefore many of my colleagues condemn it.

It is an error to condemn anatomic and physiologic rest in perityphlitis without extensive trial, for it requires the highest skill and abundant experience to form a correct judgment in many cases of perityphlitis as to the appropriate time to operate. For example, I find considerable opposition among physicians in consultation in cases of perityphlitis in regard to the administration of cathartics in acute and incipient cases. I argue with them that a cathartic in acute perityphlitis is about the worst form of malpractice. It makes the perityphlitis worse by distributing the sepsis over new areas of peritoneum and increases peristalsis, and thus increasing the pain while it gives the patient no relief from his perityphlitis. Such a practitioner mistakes the result of the perityphlitis (peritonitis) for perityphlitis itself. What the perityphlitis patient requires is anatomic and physiologic rest, no food and minimum quantities of fluid per mouth; however, ample injections of normal salt solution per rectum to control thirst, and rather opium to quiet the pain, until when? Until recovery, or until he is ready for an operation in a stage as quiescent as possible. During twenty-five years of practice I have been infected in the fingers and hands about ten times. If I worked with the hand with the septic finger, all day, at night it was worse; it throbbed, ached and became swollen. If I placed the hand in a sling — semi-anatomic and physiologic rest — it would improve, but, with a night's anatomic and physiologic rest, it was in a favorable condition in the morning. We can save large numbers of patients from dangerous and unsatisfactory operations by anatomic and physiologic rest. They can be bridged so that operations will not be required during severe local and general sepsis.

Physiologic rest consists of minimum function of viscera. When one considers that every abdominal visceral tract — intestinalis, urinarius, vascularis, lymphaticus, genitalis, nervosus — possesses the four common functions of sensation, absorption, secretion, peristalsis, and all the visceral tracts are connected with the peritoneum, it becomes evident that valuable aid may be rendered the patient by controlling the visceral functions. The four great functions (peristalsis, absorption, secretion, sensation) of the tractus intestinalis, *e. g.*, are practically produced and maintained by food and fluid. In cases of acute peritonitis, no fluid or food should pass per os. All required fluid should be administered by means of a fountain syringe, by means of slow, drop by drop, rectal irrigation. By this method all visceral peristalsis is diminished, and pain subsides. Intestinal as well as genital peristalsis distributes sepsis. The two visceral tracts which should pursue maximum activity in peritoneal disease are the tractus vascularis and tractus urinarius. Both the vascular and urinary tracts may be treated alike effectually by the same method,

viz.: gradual, slow, rectal irrigation with normal salt solution — 8 oz. per hour.

This lends volume, that is, vigorous peristalsis, to the vascular system and forces abundant elimination through the kidneys. The peristalsis of both tractus urinarius and tractus vascularis are vigorous, yet neither practically disturbs the peritoneum sufficient to distribute sepsis. There are few diseases which are controlled so effectually by anatomic and physiologic rest as peritonitis. The army of leucocytes of the peritoneum have almost plenipotentiary power in: (1), imprisoning, *i. e.*, building barriers of peritoneal exudates; (2), digesting, *i. e.*, destroying, and (3), sterilizing, *i. e.*, isolating, bacteria if the peritoneum be placed in a peritoneal splint, or rather in a state of anatomic and physiologic rest. The general surgeon appears to realize that the inflamed joints demand anatomic and physiologic rest, but seldom does he apply the principles to a fractured (desquamated) peritoneum. However, it is not strange that the inestimable value of anatomic and physiologic rest is overlooked by both the general surgeon and practitioner, since practically nothing in the medical colleges is taught on the important subject of anatomic and physiologic rest. The modern physician is gone to seed on technic. Surgical technic is the wailing cry of the medical college instead of the grand principles of physiology and pathologic physiology. In abortions accompanied with peritonitis, the cruel and unusual punishment, the uselessness and the brutal fatality of the sharp curette within the uterus has been demonstrated a thousand times; but as a young practitioner remarked, even the gynecologic books herald little warning of its immediate or remote damages. Practically, the sharp curette should be used within the uterus for diagnostic purposes only. Vastly more patients would be saved in abortions and salpingitis, if the tractus genitalis was more frequently placed in anatomic and physiologic rest. Anatomic and physiologic rest presents a double-edged sword of utility, for it is not only the most effective and safe remedy to avoid dangerous operation, but it is the most effective and safe method to prepare the patient for safe operations.

External to the peritoneum, observe the value of anatomic rest in inflamed joints, spondylitis, fractures. That anatomic and physiologic rest aids in the formation of thrombosis and embolism, I doubt.

The great principles gained by anatomic and physiologic rest are: (1) the lymph stream, especially in the peritoneum, is slowed, the muscular action required to force it with sepsis in the general system being practically absent. (2) Pain is diminished by checking muscular action and especially peristalsis. (3) In peritonitis, peristalsis not only enhances the lymph stream, but mechanically distributes germs over extensive areas in the abdominal cavity. (4) Anatomic and physiologic rest aids to circumscribe infection and save the patient from operation and death. (5) Anatomic and physiologic rest is one of the most excellent therapeutic agents to prepare patients for safe and successful surgical procedures.

TARSAL INJURIES.

BY JOHN G. W. KNOWLTON, M.D., EXETER, N.H.

UNDER the head of injuries to the tarsus, the writer wishes to draw attention to simple, noncomminuted fractures without external wounds.

The above paragraph might as truly read, injuries to the tarsus which the patient considers and describes as a "very bad sprained ankle."

Of the seven (7) tarsal bones, this paper will deal only with the os calcis and astragalus, as the others seldom suffer injury except by severe crushing of the whole foot, when two or more bones are injured and usually in connection with an external wound.

The difficulty the writer experienced in the diagnosis and the importance of consulting the x-rays are the reasons for presenting these cases to the society.

SIMPLE FRACTURES OF THE OS CALCIS.

CASE I. The patient was a male, thirty-six years old. He is a carpenter. While at work, standing on a step ladder, it slipped, and the patient fell about eight feet, striking the floor on his right foot. He noticed considerable pain in his foot, but continued working for an hour. The patient was seen next day, complaining of a "sprained ankle." There was considerable swelling of the foot, especially of the posterior and external surfaces. Tenderness was marked over this area, but no bony deformity, no abnormal mobility, and no crepitus could be detected. A plaster bandage was applied and cut the same day.

For several days after the accident the conditions of the first examination prevailed. There was great discomfort when the bandage was removed, pain on motion, movement somewhat limited and considerable tenderness.

An x-ray examination was advised and made. The radiogram showed a fracture into the posterior surface of the os calcis about an inch long.

The plaster was removed and a new one applied, with the foot slightly flexed. At the end of six weeks there was a good callus and movement without pain. Crutches were continued two weeks longer.

CASE II. The patient was a linesman, who fell from a height of about twenty feet, striking the ground on his right heel. He was unable to work on account of pain and disability of function of the foot. He was seen a short time after the accident. There was considerable swelling and ecchymosis about the heel. Examination showed bony deformity, abnormal mobility and crepitus. The x-ray confirmed a diagnosis of simple fracture of the os calcis.

SIMPLE FRACTURE OF THE ASTRAGALUS.

CASE III. The patient was a male, seventeen years old, and weighing about one hundred and eighty pounds. While standing on the ground, watching an athletic contest, he became enthusiastic as one of his friends won an event, and throwing his cap in the air, he followed it, but he came down in a little hole. He did not fall. He felt a sudden pain in his left foot and, without assistance, hobbled to a carriage, about three hundred yards distance.

The patient was examined within an hour of the accident. He said he had sprained his ankle, and the foot did look like a sprain. There was very little swelling, so that the bony landmarks were prominent.

There was no bony deformity, abnormal mobility or crepitus. The whole surface of the ankle was tender.

No fracture was detected. A bandage was applied and crutches ordered. The following day the physical conditions were the same, with an increase of swelling and pain on motion. A plaster bandage was applied and cut the same day. On the third day after the accident, an x-ray examination showed a longitudinal fracture on the posterior and external surfaces of the astragalus, with slight separation. The tips of the malleoli were intact. Examination of the foot showed ecchymosis on the external surface. Slight tenderness over the point of the fracture.

Three weeks from the time of the accident the patient could move the ankle joint freely without pain; there was no tenderness over the seat of injury. X-ray showed beginning union and the bone in good position. At the end of six weeks the patient left, with a plaster bandage and crutches, which he continued for three weeks, the foot being moved each day.

Case IV. This patient, a boy of sixteen, injured his right foot Oct. 1, 1906, while jumping. At the time of the accident he was wearing spiked shoes and in the act of jumping caught the spikes of his left shoe into the skin above the right knee, throwing him on to his right foot. He could not bear his weight on his foot. It was very painful.

Physical examination showed two long superficial lacerated wounds above the right knee. All the bony landmarks of his ankle and foot were prominent. There was no abnormal mobility or crepitus. There was slight swelling below the external malleolus and the outer surface of the foot was generally tender. There was no apparent fracture. The foot was held in a pillow and side splints for three days, then a plaster bandage was applied. At the end of a week the foot showed a slight broadening of the malleoli, deep ecchymosis below and posterior to the tip of the external malleolus and exquisite tenderness on slight pressure posterior to the tip of the malleolus.

The patient was urged to have an x-ray examination, but he refused. A fresh plaster bandage was applied. The patient was told that he had a fracture of the astragalus and that it would be necessary for him to use crutches for at least four weeks. He then said that he wished he had had a picture taken.

The difficulty in the diagnosis of tarsal injuries arises from the anatomical arrangement of the bones.

The bones are small, firmly wedged together, held by and practically encased in very strong ligaments. The articulatory surfaces are covered with synovial membrane. The bones are classed anatomically as spongy bones, having the cancellous tissue surrounded by a thin shell of compact osseous tissue.

On account of this arrangement the bones are strong and seldom are injured. The usual seat of injury in the region of the ankle is higher up, about the malleoli of the fibula and tibia. The usual injury to the tarsus is a compound comminuted fracture of the bones.

A simple fracture, with or without a free fragment of only one bone, although not rare, still is uncommon. Such an injury is usually caused by a fall.

In three of the cases reported the apparent cause was slight and the resulting bony deformity, as far as one could feel, was *nil*. With the exception of tenderness, there were no physical signs of fracture. There was no free fragment of the bone, so abnormal mobility and crepitus were not detected. Under ether it might have been possible to manipulate the bones, so that abnormal mobility would have been detected, but even then it is doubtful if it would have been possible to find out the exact location of the fracture.

The usual history of such case is as reported: the patient injures the ankle in some simple way, it is very painful and, although he considers it a bad sprain, yet he expects the doctor to find out how bad the injury really is. A thorough examination is made, and although there is no apparent fracture, yet one hesitates to make a diagnosis of sprain.

Many times the only sign present to aid in the diagnosis of fracture is localized tenderness. But there is no doubt that continued tenderness in connection with injuries of the ankle is very suspicious of great injury, namely, of the bones rather than of the ligaments.

The symptoms of an uncomplicated sprain are swelling, pain on motion, ecchymosis and tenderness, all of which disappear quite rapidly. The symptoms of fracture include the above and, in addition, real deformity, abnormal mobility and crepitus. But there are fractures such as three of those brought to the attention of the society, that have only the character of sprains and no conclusive evidence of fracture. Even if we considered tenderness to be efficient evidence of fracture, are we not still in doubt as to the particular part of the bone affected, and as to the result to be expected? Under these conditions the x-ray opens a new door, for it will or will not confirm our diagnosis and render great assistance in our prognosis.

Before leaving the subject of tarsal diagnosis, mention should be made of the frequency with which the laity confounds all swellings in this region with sprained ankle. This is especially true of tubercular disease of the os calcis or astragalus. Recently a case came under the writer's observation of such a case, in which a tubercular abscess over the astragalus was about to break. Trauma of the bones and ligaments of the tarsus may result in tubercular disease, but the patient goes on for some time thinking it an uncomplicated sprain. If the diagnosis is not clear, then the x-ray will tell the story of the invasion of the tubercle bacilli by the picture of necrotic bone or thickened ligaments. Single fracture of the os calcis with a movable fragment is rather common and the diagnosis is usually easy.

The usual injury of the astragalus is a comminution, by being crushed between the lower end of the tibia and the os calcis. Dislocation of the astragalus is also rather common. The surgical deformity is so apparent that the subject will not be considered at length.

Cases of single simple fractures of the cuboid, scaphoid and cuneiform bones have been reported, but they are uncommon.

It is safe to say that all injuries occurring about the joints should be investigated by the x-ray, when they are at all obscure.

In the treatment of injuries of the tarsus, the

important procedure should be, first, hold the foot in the proper anatomical position, and second, encourage the use of crutches.

Immobilization can be maintained during the period of swelling by a firm pillow and side splints. Then a plaster bandage can be applied and as it gets loose a new one can take its place. After the first week the foot should be moved every second day.

Sprains should be treated according to the severity of the injury done to the ligaments. As a rule, a firm bandage during the period of swelling and massage afterwards is the treatment to be preferred. Crutches should be ordered and used from the time of the accident until full recovery in all injuries to the tarsus.

In the treatment of fractures, where there are no objective symptoms, the writer considers it advisable to have frequent recourse to the x-ray. Once, to really make the diagnosis, on which the initial treatment depends; another at the end of three weeks to show the position of the bone, and lastly, before the crutches are discontinued, in order to be sure that good bony union has taken place. Until that is assured the weight of the body should not be borne on the foot. Examination under an anesthetic will tell little, if anything, about the condition. Lastly, if separation of the bone continues and pain persists, or if there is comminution, then under an anesthetic, the bone should be wired or the fragments excised.

Medical Progress.

PROGRESS IN SURGERY.

BY J. G. MUMFORD, M.D., BOSTON.

RESULTS OF THE OPERATIVE TREATMENT OF BREAST CANCER.

THE results of cancer treatment concern all men — physicians and laymen alike — almost as much as do the results of tuberculosis treatment; and any authoritative pronouncement on either subject must be received with keen interest.

Last May, in Washington, the American Surgical Association devoted more than half a day to a symposium on the "End Results following Operations for Carcinoma of the Breast," and twelve men took part in the carefully prepared discussion. The verdict of such a jury must carry conviction to the American profession, and their verdict is substantially this: that, although we have greatly diminished the death-rate from breast cancer, during the past ten years, the end is not yet. Indeed, to one viewing candidly the situation, it must appear that surgery in the case of breast cancer, though frequently effective, is but a makeshift for those who go late to the surgeon, an attempt often desperate, to eliminate a terrible evil; but that it offers good hope of cure for those who go early. Doubtless, in the end, we must look to preventive medicine for the proper solution of this problem. However, while we look, surgery is winning its triumphs; the death-rate is being lowered, and we can hold out a far better prospect of restored health in the individual case than we could a few years ago.

Says Halsted: "It is especially true of breast cancer that the surgeon interested in furnishing the best statistics may in perfectly honorable ways provide them. The most conscientious man may refuse to operate on any but favorable cases, and, by performing an incomplete operation, exclude from his list of complete operations such bad ones as he finds himself operating upon. Or the pathologist on whom he relies may classify as carcinoma tumors which on microscopic examination show dangerous spots, *i. e.*, a few epithelial cells here and there escaping into the stroma." That gently derisive estimate of the situation was made at the opening of this cancer symposium. As one studies the papers which were read and published, one feels that Halsted's estimate may indeed be true.

Nevertheless, and in spite of the lack of a common point of departure, or any correlated method of constructing their statistics, the well-known surgeons who took part in the debate furnish us with interesting material, and ground for increasing confidence. Their estimates and opinions vary, and vary through astoundingly wide limits, — ranging from those of the optimist who reports an end-mortality of 19.5% to those of the sober skeptic who admits a mortality of 79.1%. Here are the published figures:

TABLE I.

SUMMARY.

	Cases.	Operative mortality.	End mortality.	Well after three years.
Halsted,	210	1.7%	57.7%	42.3%
Oliver,	35	—	62.85%	37.15%
Greenough,[1]	376	3.6%	79.1%	20.9%
Cabot,	42	—	78.1%	21.9%
Dennis,	(50)	—	(22)	(78%)
Willy Meyer,	80	1.25%	65.0%	35.0%
Pilcher,	18	—	72.0%	28.0%
Vander Veer,	87	—	19.54%	80.46%
Ochsner,	98	5.1%	45.0%	55.0%
Jonas,	177	2.3%	40.7%	59.3%
Jacobson,	71	—	46.4%	53.6%

The surprising variation in the reported results calls for some explanation, but any explanation, even that given by Halsted, fails to satisfy us entirely regarding the discrepancies in the figures. We read certain statements of the writers, however, statements which deserve notice; most of the debaters protest at once that it is impossible to trace the results of general hospital operations, because many of the hospital patients are lost to sight and can never be followed. In spite of such assumed impossibility, however, both Halsted and Greenough do give general hospital results, worked out with the greatest care, and deserving the highest praise. Halsted's cases, if one may judge from his own writing, include all of his private cancer patients

[1] Dr. R. B. Greenough, of Boston, by invitation, took the place of Dr. J. C. Warren in the discussion. At Dr. Warren's suggestion, Dr. Greenough, with two associates, — Dr. C. C. Simmons and Dr. J. D. Barney, — had worked up and reported the "results" of the Massachusetts General Hospital for the past ten years. In the discussion and in this writing Dr. Greenough's name is taken to stand for the work of that institution.

also; while Greenough's cases are general hospital patients only, — the patients of a great number of surgeons operating by diverse methods and through thirteen years, so that, as the author states, his figures do not by any means represent the best private work of any one of these surgeons, but gives us a basis upon which we may estimate the *average* of hospital surgery in the community. Although neither Halsted nor Greenough makes the following statement, it is a fact familiar to all hospital operators, that the class of patients presenting themselves at a public clinic show a far more serious average condition of advanced cancer than do an equal number of any one surgeon's private patients. This fact may explain the high end-mortality reported from the hospital clinic, but does not explain the wide variation of figures reported by the other surgeons from their private clinics. The figures of Dennis should be quite separately considered, because Dennis deals with fifty cases, which had passed the three-year limit. He traces their subsequent careers and shows for our satisfaction that of those persons who survive the three-year period, the chances of recurrence of the disease are but two in ten. Two interesting questions which have been much discussed seem to have been fairly well settled in this symposium, — the true value of a three-year limit; and the proper significance of the term " recurrence." Volkman, more than twenty-five years ago, established three years as the time-limit upon which to estimate cases, but such a limit now seems meaningless. Thirty months or five years would be equally appropriate. It is fair to say that the longer the patient survives after the operation, the less prospect is there of a recurrence. Ransohoff reports an undoubted case of his own, still living and well, twenty-nine years after the operation, while numerous surgeons report cases with recurrence eight, nine, ten, eleven, fifteen, seventeen, nineteen and twenty-one years after the first discovery of the disease and the primary operation. As for the place of late development of distant metastases (recurrence) we know them to be common within the chest, in the liver, in the vertebræ and in the long bones, as well as in the field of the original operation and in the opposite breast. A true recurrence or metastatic development of the peculiar forms of breast cancer should puzzle no expert pathologist. But physicians should remember that coincident or long delayed development of cancer in the pelvic organs, intestines, the genito-urinary apparatus, the rectum and the ends of the extremities, have no direct association with the cancer of the breast. When we see reported cases of uterine cancer following the removal of breast cancer, and *vice versa*, we should reflect that the writer records a coincidence merely. These are prefatory and explanatory remarks prompted by the interesting composite of information furnished by the papers, and we shall have to make more explanations and qualifications later; but a somewhat careful analysis of the discussion brings to the surface certain interesting factors and propositions covering the whole range of breast-cancer surgery.

Matters of pathology, of diagnosis, of metastasis, of time before recurrence and of methods of treatment bear closely on the question of eventual immunity, and with such matters it is well to concern ourselves here.

Halsted's discussion of the *pathology* of breast cancer, especially its method of dissemination, is important. He accepts the views of W. S. Handley, who published his interesting conclusions some two years ago, to the effect that metastases do not arise from particles swept along in the blood and lymph channels, but come about by a more slow and subtle method, through the actual coterminous growth of cancer cells along the finer vessels of the lymphatic plexuses. This " permeation " takes place almost as readily against the lymph stream as with it, and spreads in much the same way as would a thick injection fluid introduced by a syringe into the tissues. Cancer thus advances like an invisible annular ring, extending like a ripple in a wider and wider circle, within the circumference of which healing processes take place, so that the area of permeation at any one time is not a disk but a ring, though there may be left behind within the circumference isolated islands of the new growth, which, on careful dissection, appear as skin cancer nodules. In this way, gradually, great areas of the body's surface may be involved, including the whole head and trunk, the arms half way to the elbows and the thighs to just below the trochanters, should the patient live long enough. This gradual and wide manner of skin involvement, though occurring late in the disease, is a strong argument in support of Halsted's well-known contention that a great area of skin over the entire breast should be removed in a radical operation. Cancer is found to spread along the planes of deep fascia also; gradually advancing, following always the fascial routes, and by continuity, until it attacks distant organs and parts, — the femur, the humerus, the liver, by way of the deep fascia, the linea alba and the round ligament; the brain by the lymphatics, accompanying the middle meningeal artery, and other parts and organs in similar fashion. Such is the method of " metastasis "; but before this occurs even, the diseased tissues near their central focus assume a certain form, quite characteristic, resembling a biconvex lens in shape. " The thin circumference of the lens situated often far beyond the limits of the breast, is formed by the cancer-filled lymphatics of the fascial lymph plexus. As one approaches the centre of the lens, which corresponds to the primary growth, the adjoining layers — the subjacent muscles on the one hand, and the subcutaneous fat and skin on the other — are invaded by cancer to a gradually increasing depth."

Halsted, with many other thoughtful surgeons, admits this conception of the spread of cancer, and one sees the important bearing of this con-

ception on the subject of radical and searching operations.

The question of cancer cysts also is of grave concern to Halsted, and he dwells earnestly on the importance of making the diagnosis of malignancy in these cysts at the operation itself, if malignancy be present in cases previously assumed to be benign, as so often happens. Halsted mentions further an extremely interesting pathological condition, bearing upon Handley's teaching,— a condition of cancerous axillary glands without apparent involvement of the breast as a starting point. He refers to two such cases, in which axillary dissection had been done before the patients came to him. In both cases, some months subsequent to these operations, breast cancer frankly declared itself.

Greenough also makes certain interesting observations on the pathology of breast cancer, especially as regards the malignancy of varying types. His findings in the study of 376 cases are not novel, but his percentages are interesting, and in reading the percentages, one should remember that he deals with a great number of very advanced cases; indeed, he includes in his list a large group of hopeless cases, for which palliative operations alone were attempted — the removal of foul and sloughing masses of disease.

Medullary cancer is the most frequent form of breast cancer, unfortunately, and shows the highest percentage of fatality, both immediate and ultimate.

Scirrhus stands next with an end result nearly five points better. Adeno-carcinoma is far less malignant, while colloid cancer is the most favorable form of all.

The following table tells the story:

TABLE II (GREENOUGH).

VARIETIES OF CARCINOMA.

	Cases.	Cases surviving radical operation.	Cases free from recurrence.	Per cent.
Medullary,	136	104	19	18.2
Scirrhus,	46	43	10	23.0
Adeno-carcinoma,	24	21	10	47.6
Colloid,	4	3	2	66.0
Cancer, variety not specified,	127	107	18	16.8
No pathological report,	39	31	8	25.8

TABLE III (HALSTED).

CARCINOMA OF THE BREAST — PATHOLOGICAL VARIETIES.

	Number of cases.	Cured cases.	Per cent.
Cancer cysts,	6	2(1?)	33.3
Adeno-carcinoma,	32	24	75.0
Medullary carcinoma,	25	12	48.0
Circumscribed scirrhus,	28	13	46.4
Small infiltrating scirrhus,	80	30	35.5
Large infiltrating scirrhus,	39	8	20.5
Total,	210	89	

Greenough points out also that out of eight cases of Paget's disease but one survives, — an end-mortality of 87.5%. On the other hand, cancer developing in the lactating breast (commonly regarded as an extremely grave condition) showed an end-mortality of but 71.5% in seven cases. Cancer developing during gestation is probably more fatal than during lactation.

Halsted's remarks on glandular involvements are extremely interesting. He deals with a total number of 232 cancer cases, and of these 168 only showed any evidence of diseased glands in the axilla. That is to say, we may expect to find, in a large group of cases, the axilla involved in 72.4% only. But this must not mislead us, for in nearly a quarter of Halsted's cases, which were free from axillary involvement, metastasis occurred sooner or later; so that he is driven to remark, " We must bear in mind, however, that surely in some, and probably in many if not in most, of the axillæ recorded as negative there was disease." Regarding these glands Greenough says, " It is quite possible that in early cases, without palpable enlargement of the glands, the disease is entirely within the glands and can be readily removed; whereas, in glands which are palpably enlarged the disease has extended through the capsule and along the lymphatic trunks and become disseminated through the axillary fat to such an extent and in such minute strands that complete removal is very difficult, if not impossible of achievement." Our understanding of Handley's theory of cancer permeation makes highly probable the supposition of Greenough.

(To be continued.)

Reports of Societies.

EIGHTH ANNUAL MEETING OF THE AMERICAN THERAPEUTIC SOCIETY.

HELD AT WASHINGTON, D. C., MAY 4, 6 AND 7, 1907.

[Continued from No. 18, p. 608.]

DISCUSSION.

DR. ROBERT REYBURN, Washington, said that there is no class of patients with whom he has greater sympathy. According to his experience, physicians are peculiarly liable to contract drug habits.

DR. OLIVER T. OSBORNE, New Haven, said that the method of control was a good one and the provisions of the Maine law should be more generally known in order that interest to take similar action might be aroused in other states. Upon motion it was ordered that a copy of the law be sent to each member of the society.

DR. V. E. HENDERSON, Toronto, inquired as to the necessity of having the order of committal made before a superior justice.

DR. L. F. KEBLER, Washington, spoke of the advertised " cures " for drug habits and the method of treating patients by correspondence. Prescriptions sent through the mails are not exempt under the law. He inquired as to the number of *habitués* in the United States. He understood that there was about 1 in every 125 persons.

DR. F. E. STEWART, East Orange, told of preparations which were advertised and sold with the deliberate intention of setting up the opium habit.

DR. GERRISH, in closing, said that a Superior Justice was named probably to give dignity to the committal proceedings. He believed that any judge of a court of record could do the work. A valid criticism of the law was that those who were specified to examine the

patients prior to their release, by reason of their residence, had to take long and expensive journeys. This could be obviated by designating local county officers to do the work. He did not know the number of *habitués* in this country. Over 50% of the victims he had treated were physicians. He described the events leading up to the passage of the Maine law.

THE VALUE OF PHYSICAL TRAINING IN THE TREATMENT OF NEUROTIC PATIENTS.

Dr. B. E. McKenzie, Toronto: The first step is to make a positive diagnosis to determine whether organic disease is present. In the management of the neurotic there must be no vacillation on the part of the physician. He must separate his patient from all harmful surroundings and subject her to a kindly but firm discipline. She must be turned from introspection and egotism and taught to be cheerful, self-reliant, active and altruistic. The ordinary "rest cure" falls short in that it is merely negative. For discipline, encouragement and development, physical training in the gymnasium and on the playground is a most effective agency. It requires the assistance of a thoroughly trained and tactful director. Many excellent results are reported.

Dr. Oliver T. Osborne, New Haven, said that he had visited the institution under Dr. McKenzie's charge and heartily commended his work and methods. Neurotics form a difficult class of patients, but much can be accomplished by persistent systematic effort. He commended the gymnastic training advocated by the essayist. Suggestion, also, should not be overlooked.

PRINCIPLES UNDERLYING THE TREATMENT OF TUBERCULOSIS.

Dr. Francis M. Pottenger, Los Angeles: Dr. Pottenger classifies the measures employed in combating tuberculosis under six heads: 1. Those which aid in bringing about immunity by endeavoring to restore as far as possible the normal resisting power of the patient. Fresh air, hygienic measures, proper diet, hydrotherapy, favorable climate and suitable tonics. 2. Those which aid in bringing about immunity by artificially stimulating the body cells to the production of specific protective substances: vaccination or treatment with such products as tuberculin. 3. Those which aid in establishing immunity by supplying specific protective substances which were produced by vaccinating some animal such as the horse or cow: antitoxic sera. 4. Those measures which cause an increased flow of blood or lymph to the seat of infection: Bier's hyperemia, Finsen light, poulticing, local congestive action of tuberculin. 5. Remedies and measures which relieve symptoms. 6. Measures which relieve secondary infection.

DISCUSSION.

Dr. B. E. McKenzie, Toronto, emphasized the value of fresh air and sunlight in the treatment. He commended the paper as being thoroughly scientific.

Dr. V. E. Henderson, Toronto, spoke of the open-air treatment. We should also make use of other rational methods which promise benefit to the patient. Wright has shown us how we can do this and also in some degree measure the patient's improvement.

Dr. H. Van Rensselaer, Albany, spoke of the opsonic index as a guide for fixing the dose of tuberculin. He asked Dr. Pottenger to describe the technic used in obtaining the index. If it were not correctly determined, harm might be done by the administration of an improper dose of the remedy.

Dr. Pottenger described the technic. Much difficulty has been encountered with the method here, largely because of the poor literature on this side and inadequate preparation on the part of those who try to do the work. The discovery is one of the greatest in modern medicine. Dr. Henderson had struck the keynote. Harm is done by relying solely on fresh air and sunlight. He had for years believed that much more can be done. There are no more specifics than in any other chronic disease.

ON PYROLIGNEOUS ACID AND ITS INTERNAL USE IN ARTHRITIS DEFORMANS.

Dr. Louis Kolipinski, Washington: Dr. Kolipinski characterizes pyroligneous acid as a forgotten drug, which, however, well deserves recognition as a therapeutic agent. He describes it and explains its chemical composition. It is a dark red liquid, turning black on exposure. It has been called "liquid smoke." After discussing its physiological action, toxicology and its uses in the earlier days, he cites cases in which it has proved efficacious in his hands in the treatment of arthritis deformans. The restoration of function is well shown in the use of the hand and fingers. The claw-like posture, the extended position in which the member is held, the constant watchfulness to protect it from contact are no longer seen. Flexion and extension return and the hand resumes its duties. The patient ceases to complain unless this continues from habit.

DISCUSSION.

Dr. Arthur H. Hall, Washington, related a case of joint disease in which he had used pyroligneous acid with marked success after the usual methods had failed. The joints affected were those of the jaw and right shoulder. Two drams of the acid in water were given every three hours. Before 8 oz. had been taken the patient demonstrated that pain had disappeared, and after a time motion in the affected joints was satisfactorily restored.

Dr. H. C. Wood, Philadelphia, said that the use of undeservedly disused medicines should be revived, and he who revives them deserves credit. Unfortunately, however, in this case, from a pharmacological standpoint, the recommendation is a step backward, inasmuch as pyroligneous acid is a complex substance containing components, some good, some indifferent and some harmful. The tendency of to-day is toward the use of simple drugs. He who orders such complex substances practices polypharmacy. Pyroligneous acid depends mainly for its activity upon phenol and cresol. It is true that they have proved useful in certain cases of joint disease.

Dr. A. D. Blackader, Montreal, expressed doubt whether valid conclusions as to the value of the agent in such a resistant affection as arthritis deformans could be drawn from a few isolated cases. Sometimes the disease gets well spontaneously, and at others it becomes quiescent and later breaks out again. He agreed with Dr. Wood as to the inadvisability of using so complex a substance. Undoubtedly, this class of drugs is useful in a few cases of chronic joint disease.

Dr. Oliver T. Osborne, New Haven, suggested that some of the good may have been due to disinfection of the bowel, as in the case of epilepsy mentioned. He discussed the subject of bowel disinfection. He believed that something can be done in this line, and the beneficial action of such remedies as pyroligneous acid in joint pain may in some degree be due to this effect. He did not see how it can do any good in arthritis deformans after bone has been deposited. Some of these cases get well and no one can tell why or how.

DR. KOLIPINSKI, in closing, said that in the light of his experience he could not do otherwise than believe in the efficacy of the remedy. He appreciated the force of Dr. Wood's criticism, however, and intended to make the individual components of the acid a subject of further study.

THE VALUE OF CHEMICAL SUBSTANCES USED HYPODERMATICALLY TO ANTAGONIZE MORBIFIC PROCESSES.

DR. JOHN BLAKE WHITE, New York: Hypodermic medication was introduced by Wood, of Edinburgh, as a strictly local measure. Hunter, of London, first recognized that it can be used for systemic effect, and now it is universally believed that localization of the injection is not necessary. There is little certainty about the dose by stomach. Quinine has been given hypodermatically in malarial fever in one fifth of the dose given *per orem* with much better effect. It is possible that some morbific processes are combated by antitoxins produced by substances injected hypodermatically. The results achieved by him in fifteen years have convinced him of the superiority of the hypodermic method. Remedies given thus are not changed by the gastro-intestinal juices; they can be given to those unable to swallow, and where irritability of the stomach exists. The remedies selected should be soluble and unirritating. One should be prepared for idiosyncrasy. Dr. White exhibited a syringe which could be kept aseptic more easily than those in general use.

DISCUSSION.

DR. S. L. DAWES, Albany, said that quicker and more satisfactory results can be obtained if the solution is injected at the temperature of the body. Also, the drug used should be in perfect solution. These points are often overlooked. He asked Dr. White whether he could get as good results from the injection of chemical substances in diphtheria as we can get from the use of antitoxin.

DR. OLIVER T. OSBORNE, New Haven, inquired as to the composition of the solution injected by Dr. White in cases of sepsis.

DR. WHITE described the solution, and answered the question of Dr. Dawes.

THE IMPORTANCE OF A KNOWLEDGE OF THE NATURAL COURSE OF DISEASE IN ESTIMATING THE EFFECT OF THERAPEUTIC MEASURES.
